THE IMPORTANCE OF THE ADOPTION OF ELECTROCARDIOGRAPHY AND ORTHODIAGRAPHY AS ROUTINE MEASURES IN THE MANAGEMENT OF DISORDERS OF THE HEART.*

BY LOUIS FAUGÈRES BISHOP, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY; PHYSICIAN TO THE LINCOLN HOSPITAL, NEW YORK.

IT seems to me that the longer I am in practice the harder it becomes to lecture satisfactorily on the subject of my work. When a man first fits himself for a particular occupation his knowledge is a fairly definite entity, and can be imparted in a systematic manner. As he works year after year the systematized knowledge is replaced by acquired skill and he forms judgments without a conscious review of facts.

In the beginning he meets a medical problem by an examination and by referring the findings of this examination to a very clearly defined body of knowledge. This method is more or less conscious. After training that comes from years of work, the examination is made in a more discriminating manner, emphasizing the important points and eliminating unnecessary waste motions, and the findings are unconsciously referred to a subconscious knowledge that is not easily reproduced. The young teacher can train the young student fairly well in

*Read at the annual meeting of the First District Branch of the Medical Society of the State of New York, held at Tuxedo Park, October 17, 1918.

those things which are a matter of conscious knowledge. When a man has gone far enough in his profession to acquire skill, he finds it very difficult to impart that knowledge even to practitioners of his own maturity. Indeed, in the whole history of medicine there have been only a very few great doctors and surgeons who have been able to teach the profession even a small part of their art.

With regard to the modern methods in cardiac disease it is often asserted that now at last definite methods have been substituted for the intuitive opinion, founded chiefly upon judgment and experience.

The general consultant of the old school had acquired his position in the profession and his chair of medicine in the school on account of his personality and native ability to examine and advise wisely in regard to serious medical situations. He gathered facts through as many channels as possible. In heart cases he formed his judgment from the sounds of the heart *and all the attending circumstances* and gave an immediate and categorical opinion. The profession always attributed to him a wonderful power of hearing, which he himself never claimed, knowing as he did that his judgment was founded upon all the attending circumstances.

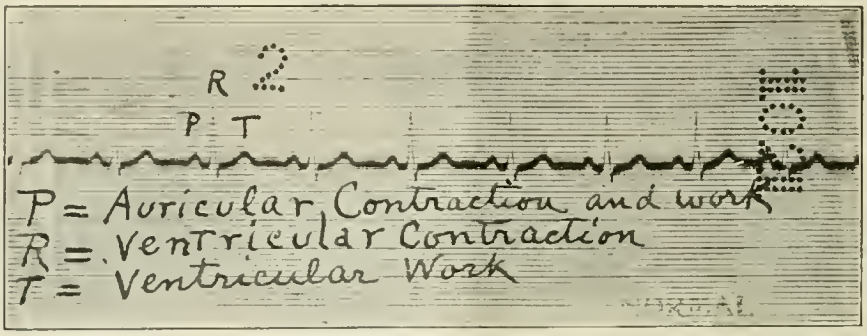

Fig. 2.—A normal electrocardiogram with a simple explanation of the three most important waves.

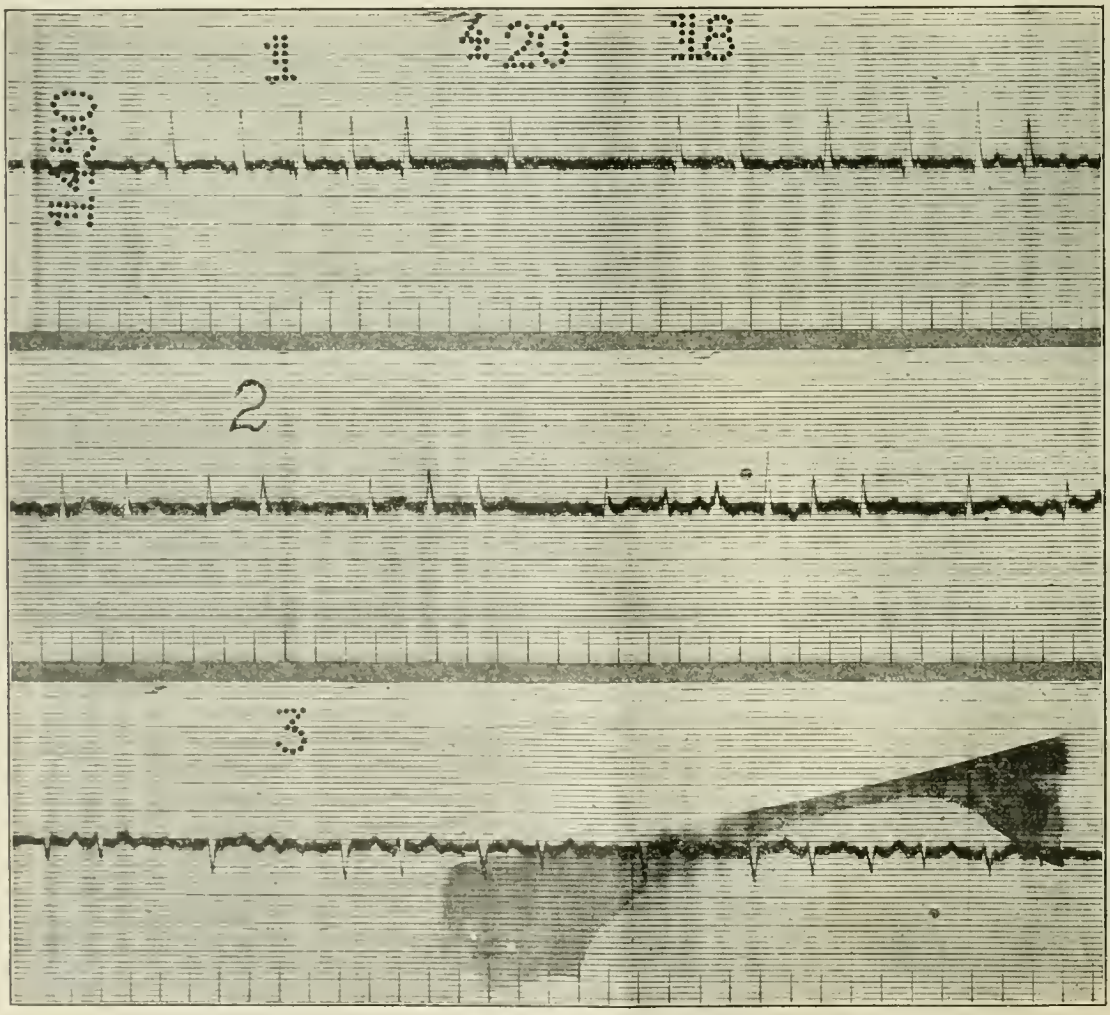

Fig. 3.—Electrocardiogram in a case of auricular fibrillation.

The same general facts remain true as to the modern examination of the heart patients by newer methods. When all is said and done, the conclusion must still rest upon the interpretation of the trained practitioner of the tracings, *x*-ray picture, and laboratory findings, as checked up by a knowledge of the patient himself.

The more findings we have the more correct is our judgment, because it is always possible that some fact may entirely modify the conclusion. The absurdity of drawing conclusions from a single laboratory fact can be no better shown than by something that happened to me some years ago.

At that time I owned and controlled a large clinical laboratory. A man had come to me with very serious heart and kidney trouble and I had sent a specimen to the laboratory. I put the man on a strict regimen and a few days later he sent another specimen. My assistant wishing to have an afternoon and evening off, had gone back to the laboratory later at night to complete the examination of the specimen. At midnight I was aroused by the telephone and my assistant said, "You had better look up your patient right away, because there has been a great diminution of urea in his urine." I thanked my assistant for his conscientiousness in notifying me immediately and turned over and went to sleep. The facts of the case were that I had temporarily stopped the nitrogen intake of my patient and, of course, there was a corresponding diminution of nitrogen output. The point is that no single technical finding is a safe guide to a conclusion, except in so far as it is interpreted in the light of attending circumstances.

With regard to electrocardiography and the interpretation of *x*-ray outlines of the heart, it is too much to expect that the profession shall master the difficult and intricate technicality of the subject. What the profession can and should do, is to study enough examples of this kind of work so that they can judge in a general way of the meaning of these pictures.

Education can come only through repetition and the profession should be taught this matter in a practical way, which is possible, rather than in a purely technical way that is impossible. I have heard within a day or two of an Englishman who claims to teach men to fly in airplanes in five days. I know, as a matter of fact, that some teachers can teach the practical use of a language in a short time and also the art of dancing.

These examinations make work with heart patients so much more definite, easy and interesting that any one who has had the opportunity of following patients with series of fluoroscopic and *x*-ray pictures and series of electrocardiograph tracings would hardly be willing to do without them. I have been using them as a routine measure with

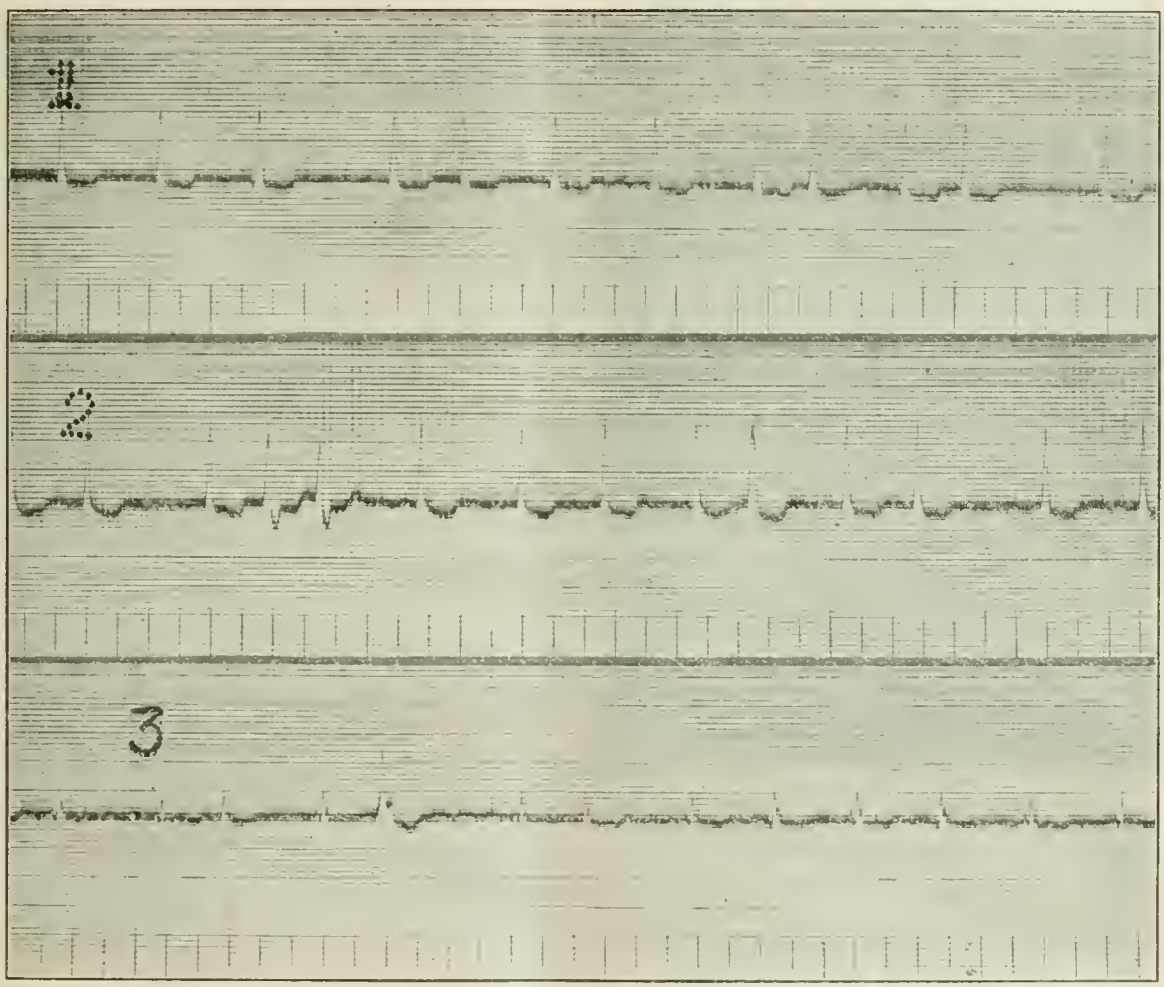

FIG. 4.—Electrocardiogram of a benign type of auricular fibrillation of many years' duration.

every heart coming under my attention and in this way have accumulated a vast quantity of findings. Every heart has an individuality of its own and every electrocardiograph is just as individual as a man's face or his signature or handwriting. If a patient comes back after a long period he can be identified by his electrocardiograph just as he could by his finger prints. As in the contraction of any other muscle, the heart muscle when it contracts becomes positive at one end and negative at the other end and thus produces an electric current, and while it is not practical to connect a wire to each muscle to demonstrate this, such a test is not necessary. The principle is similar to that of the duplex telegraph, which can carry ten messages over one wire and distribute each to the proper distributing station. In a similar way the different currents run through the heart and there is no difficulty in identifying them because they happen

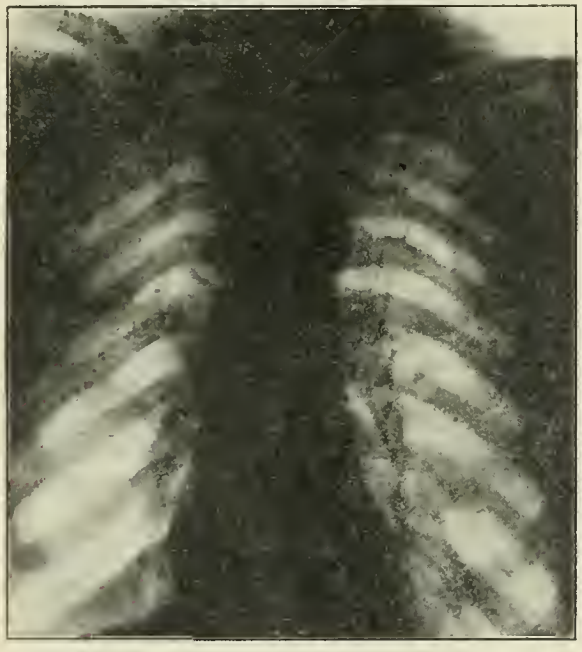

FIG. 5.—*X*-ray picture in a case of infantile heart

at different times and have certain definite characteristics.

Another interesting point that is one of the developments of the war is a substitute for the glass plates used in making radiographs. As the *x*-ray work begins directly at the front and it is inconvenient to carry glass, the Eastman Kodak Company has developed these films which are being shown here and which we are using instead of glass. They are light in weight, take up less space and are much less expensive than glass.

What I want to do this afternoon is to try to present the subject of the technical examination of the heart with regard to its influence on treatment, in such a way that I may impart something of practical value. There are a few things that must be committed to memory. You should learn the names of the seven varieties of disorders of the heart beat, as these have become the standard by which we work toward the closer classification of irregular hearts.

These are sinus arrhythmia, heart block, premature contraction, simple paroxysmal tachycardia, auricular flutter, auricular fibrillation, and alternation of the heart.

1. *Sinus arrhythmia* is chiefly important because it is not of serious import and occurs as a physiological phenomenon in young children. It can be reproduced at any time in comparatively young people by taking a long breath. It consists of a difference in the length of the interval between the beats. When exaggerated in children, it has sometimes led to the suspicion of myocarditis and the children have been treated as invalids when they should have been playing out of doors. That can no longer happen under the advice of those who understand the use and interpretation of the polygraph.

2. *Heart Block.*—The impulse of the heart ordinarily begins in the auricle and is transmitted later to the ventricle, so we have the auricle and ventricle contracting in rhythmic succession. If disease destroys the muscular contiguity or conductivity, we have the auricle and ventricle out of relation to each other. This has received the name of heart block, and is beautifully shown by the electrocardiograph and it is due to this instrument that our knowledge of this condition exists.

3. *Premature Contraction.*—In many people suffering from disturbed metabolism we find the heart apparently missing an occasional beat. The fact is, however, that the heart is not as a rule missing a beat, but the beat is occurring prematurely and may pass unnoticed, while the succeeding beat is very large and emphasizes the length of the quiet interval. This is called premature contraction. It is a condition that sometimes worries people but which is not of much account. It is caused by a contraction of the ventricle when there is no blood in it, so that there results a wide excursion of the muscle which is not represented by any wave in the circulation. Fig. 1 is an electrocardiogram of a very curious case in which every other beat is a premature contraction. The patient had a pulse of 40 as a consequence, while in reality the heart beat was 80.

I am showing you about 100 examples of the *x*-ray and electrocardiograph findings to make them familiar, but only a few can be reproduced in the transactions.

Sometimes in very sick people the heart is "all in" because of the condition of the muscles and we get a defect in one lead, but when we find a defect in more than one lead there is a serious defect in the heart muscle, a true myocarditis.

4. *Paroxysmal Tachycardia.*—When for any reason the heart abruptly becomes very rapid for a period and suddenly ceases to be rapid, we say that the person is suffering from paroxysmal tachycardia. This has been a most difficult field of investigation and is still the ground of many disputed points. However, our instruments have disproved many previously held beliefs and pointed out not a few new facts.

5. *Auricular Flutter.*—One of the most recently recognized conditions is the extremely rapid though regular auricle, usually 250 to 300 per minute. It is always revealed by the electrocardiograph and occasionally by the polygraph.

In auricular flutter the heart may beat 300 a

minute with perfect regularity. Sometimes in these cases the ventricle is regular and sometimes it is not. Many people do not know the significance of a normal electrocardiogram. I do not want anyone to go away without being able to recognize a normal electrocardiograph. This is shown in Fig. 2.

There are five waves, the P, Q, R, S, T. The P wave represents the auricular contraction; the R, the ventricular contraction; and the T, the ventricular squeeze. The auricle contracts gently and pushes the blood into the ventricle. The high point represents the contraction of the ventricle. When the heart at first contracts on the blood it does not move the blood but generates a sharp current and following this the further contraction of the ventricle squeezes the blood out and that represents the T wave.

6. *Auricular Fibrillation.*—The knowledge of auricular fibrillation is one of the most important contributions of clinical medicine that has come from the student of pathological physiology. In this condition, there is a trembling palsy of the auricle, which transmits a vast number of impulses to the ventricle and the ventricle becomes very rapid and irregular. Auricular fibrillation is the disease that yields most strikingly to the therapeutic action of digitalis.

Fig. 3 is a drawing from the case of a Brooklyn clergyman who had fibrillation of the auricle. After rest and appropriate treatment the tracing has become practically normal.

Fig. 4 shows a type of fibrillation which is quite benign. It is from a man who is the head of the accounting department in a large factory. At times he has discomfort and then he takes a little digitalis. Taking a little digitalis from time to time controls his fibrillation.

Alternation of the heart can be detected in many instances only by the polygraph. It is of extreme importance because it is a striking evidence of failure of the heart muscle. It consists of an alternation in the size of the beats.

It is sometimes said that the complete examination of the heart is superfluous in so far as it does not lead to treatment. There was formerly some truth in this impression, particularly with regard to heart troubles, because heart work in the past has always been done by men who are essentially diagnosticians, while therapeutics of heart disease was left in the main to men who were essentially practitioners.

The crude diagnosis of disorders of the heart has often led to the placing of all marked irregularity in the general category of myocarditis. This has led to the logical conclusion that because the muscles were the seat of inflammation they must be rested and subjected to as little drug treatment as possible.

The complete examination by modern methods, divides the irregular hearts into certain groups, each one of which requires a different form of management and presents a different problem. The important point is that the heart is not involved as a whole but is disordered in regard to some particular structure which constitutes but a small part of the whole bulk of the heart.

A better understanding of the irregular heart has led to much more confidence in the outcome of heart diseases.

Considering the whole group of valvular disorders, the most important method of examining is found in the *x*-ray. The *x*-ray picture taken at six feet, with the plate near the body, gives a true outline of the heart and the fluoroscope inspection of the heart gives a good idea of the activity of the various chambers. This is far superior to information obtained by auscultation and percussion. It is known to most practitioners that cardiac hypertrophy is beneficent and the only enlargement of the heart this should be a source of anxiety is that due to dilatation.

In radiography of the chest the heart and large vessels appear as a flash-shaped shadow. When observing them through the fluoroscope, the heart is seen to pulsate. The right portion, represented by the curved outline to the right, resting on the diaphragm, undergoes a slight presystolic pulsation, while the upper right border shows a slight systolic enlargement. The lower left border shows a systolic decrease in size, while the upper border shows systolic enlargement.

In the outline of the heart we should recognize two distinct curves on the right and three on the left. The upper right curve bounds the aorta, while the lower encircles the right auricle. The upper left part also marks the boundary of the aorta. The second, the pulmonary artery, while the lower represents the left ventricle. The right ventricle is concealed by the shadow of the diaphragm.

When the heart is drawn with the orthocardiograph these curves are distinctly indicated. It is quite easy, however, in a good *x*-ray picture to distinguish them.

The relative size of these curves gives valuable information as to the condition of the heart and they are so characteristic that in many instances it is possible to tell the nature of the valvular lesion by observing the heart through the fluoroscope.

The important element of this method of examination is that these pictures constitute a permanent record.

Fig. 5 is an *x*-ray plate presenting a type of individual who has been giving all kinds of trouble to the draft boards. He has a systolic murmur on the left upper side and no history of heart disease except that he is not very good in athletics and is a little short of breath on exertion. When he goes before the draft board all kinds of different diagnoses are made and an *x*-ray picture is finally taken and we find a heart like that in the illustration. The heart is situated almost in the middle of the chest and the electrocardiogram shows a relative right-sided predominance. This is an infantile type of heart.

When a child is born the heart, like that of a fish, is centrally located and the right and left sides are about equal in size. The left side gradually develops until we get the difference between them observed in the normal adult heart. Hence we may regard this as an infantile type of heart due to lack of development. Some of these hearts are perfectly good and capable of doing military service, and the only way in which to determine this is to find out what they can actually do.

109 East Sixty-first Street.

ETIOLOGY AND MECHANISM OF THE "PRISON PSYCHOSES."

AN OPINION AND SOME CASE STUDIES.

By LEON EMILE DUVAL M.D.,

WASHINGTON, D. C.

ASSISTANT PHYSICIAN, ST. ELIZABETH'S HOSPITAL.

FOREWORD.—In present-day medical literature one finds among many writers a tendency to offer as original material, a review or rehash of the opinions of other writers and to incorporate into their articles long extracts from the works of others. The reader who endeavors to keep in touch with the latest developments in medicine finds himself reading many pages to gain a single new or original idea. He finds that much of the subject-matter is that which he has read elsewhere, once or perhaps many times. With this thought in mind, the writer of the present article is giving brief space to the opinions of others, merely sketching the chief trends of thought which have prevailed, on order that any new ideas introduced may be compared and contrasted the more carefully.

The subject under consideration has not been as fully studied as many of its kindred subjects, so that the writer feels justified in considering it from a somewhat different standpoint than has been previously done. He does not claim to be the first to have considered it from this stand-point, but has failed to see it expressed in the literature, and hopes that it may perhaps bring him in touch with those who uphold or oppose his views, in order that he may see it through eyes other than his own.

The criticism may be (rather justly) made, that the writer has offered only a limited number of case studies in support of his views. His excuse lies in the fact that among scores of the criminal insane in this institution, less than a score of the psychoses encountered might be classified as "prison psychoses," and that among this number, but few have been intelligent and accessible enough to permit their study from the angle from which the following cases are presented.

While not a fanatic, the writer is an enthusiastic believer in the principles laid down by the psychoanalytic school. His belief in these principles is based upon the fact that an unbiased observation of mental cases, as well as of normal individual, constantly confirms these principles. It is entirely possible, of course, to carry them to extremes, but this does not obviate their usefulness. Only a confirmed pessimist can deny the excellent practical results observed in many cases treated by psychoanalysis. Those who oppose this method of treatment do so, in many cases, because of the complexes present in their own psychic makeup. The usefulness of psychoanalysis consists not alone in the therapeutic possibilities it presents, but fully as much in the insight it gives us into normal and pathological psychological states. Not every physician can be a psychoanalyst, but every one can make use of it in his practice, and be richly repaid by the deeper understanding it will give him into his cases, no matter for what reason they may have come to him.

Prominent among modern psychiatric trends is a growing tendency to study mental cases from the point of view of the individual, his peculiar possibilities and limitations. It is beginning to be comprehended that to make a diagnosis and to consign the case to some special group is not sufficient. We can not index or classify an individual case as we might a museum specimen. It is not to be denied that many mental cases correspond nicely to text-book descriptions of this or that disease-syndrome, and we are able, from these descriptions, to gain fairly correct impressions as to mechanism, prognosis, etc. Even in these "text-book" cases, however, we find wide individual variations which can not be explained by any hypothesis which can be applied to the group as a whole. These variations are explainable only as we study the individual, his particular difficulty, and his ability to readjust and form compensations. In every personality the psyche presents a content which varies from that of every other in its make-up, because of the mixture of factors peculiar to the individual, created by his life-surroundings, his various experiences, the content of his phantasy-life, with all of the many other influences which have been brought to bear upon him, and have molded his psychic life from birth. With such variation, we can not apply to any given case a lot of text-book generalities, and expect the case to follow a beaten pychic track.

In the study of mental cases we must, of course, have definite ideas about the various disease-syndromes, else we are unable to appreciate the mechanism of the individual case. But one must not allow himself to become biased by text-book ideas, or to think only in terms of this or that combination of symptoms. One must consider the individual and his problem first, and be content to let diagnoses and classifications be minor considerations. In institutional work, and for purposes of classification, it is of course necessary to apply recognized diagnoses to our cases. In justice to the individual, however, we must not think of him as suffering from dementia præcox or psychoneurosis. We must think of the case in the light of the individual's peculiar difficulties, and the manner in which we may aid him in solving them. I have obtained my best results by studying cases from the psychoanalytic standpoint, considering all of the factors and forces which have surrounded the individual, and exerted their influence on his mental life. My insight into the psychic mechanisms involved has been aided materially by the study of the works of Freud, Brill, Jones, Pfister, White, and Jelliffe.

With these considerations in mind, I wish to study the group of cases to which the term "Prison Psychosis" has been applied. As commonly understood, this term is applied to cases in which the cause of the mental upset was confinement in prison, and in which, as I understand it, no other etiological factors were present. I propose to show that in these cases other elements than the prison milieu are present, and that without these elements there would be no psychosis.

To the normal individual, prison life, with its strict discipline, unpleasant, unsympathetic environment, affords a situation which is hardly calculated to bring out the best that is in him; rather it tends to bring out his poorer traits. And the average prisoner is hardly normal, especially the

recidivist. It is no secret that the conditions in some of our prisons are far from what they should be. Such punitive measures as solitary confinement, dark cells, restricted diet, hand-cuffing to the cell door, to say nothing of rules which prevent conversation, smack of barbarism. The writer has had no experience in prison work, nor any first-hand knowledge of prison conditions, but he does know that all of the above-named measures are in use in this country at this time. In the conduct records of patients sent to the criminal wards of this institution, these punishments are enumerated time and again. I am not criticising prison methods, for I do not know the conditions under which prison officials work. I quote these things merely to show the kind of stresses to which prisoners are subjected. It is hardly to be wondered at that an individual of poor mental stability should break down under these conditions.

Among prison populations we find a large proportion of individuals of defective make-up, constitutional inferiors, and psychopaths, to say nothing of the morons and imbeciles. The prison milieu, like any other uncomfortable situation, tends to produce psychoses of one kind or another in these individuals. They are especially prone to brief episodes which are manic-depressive or dementia præcox-like in character, which clear up rapidly when the individual is removed from prison. But we find these same episodes in these individuals in many other situations; a common example is seen in recently enlisted soldiers and sailors. Army or Navy life, like that of prison, calls for strict discipline, unvarying routine, and the inability to escape it when it becomes tiresome. Another attribute of these situations is the homosexual environment. The individual with homosexual tendencies, or of homosexual make-up is laid under heavy stress, repression becomes more difficult and the possibilities of compensation are lessened. My reason for laying emphasis on this particular condition will be made apparent later on.

Prison life, therefore, subjects an individual to manifold stresses, loss of liberty, strict discipline, and homosexual environment. But as Dr. Bowers points out, hundreds of men suffer prison life and its burdens without developing mental disease, and he believes that the development of a psychosis in the prison milieu is indicative of "defective mental substrata, if not of actual mental disorder," and it seems only reasonable to suppose that there must be some other factor than the prison milieu alone. This is also true of other situations which are often called the exciting factors of psychogenetic disorders. Loss of a loved one, financial ruin, and the like are suffered by many, but few fail to react to them properly. Those who do break down in these situations are of defective stability, and are apt to fail to meet any serious problem successfully. I contend that any individual who breaks down as the result of prison confinement would fail to meet any strong mental stress, and would show the same tendency to seek flight in a psychosis. The individual may have successfully weathered all storms heretofore, but should he meet a sufficiently severe situation, one to which he could find no comfortable adaptation, the result would be refuge in a regression of the affects, as manifested by the same types of psychosis seen in the group under discussion. No normal individual will develop a psychosis as a result of prison environment. I feel safe in asserting that a psychosis developed in confinement, or for that matter any psychosis precipitated by such affective injuries as financial ruin, death of the mother, etc., indicates that there is present in the individual an internal conflict, hitherto successfully repressed, but brought to a climax by the added shock. The conflict is not always apparent, but it is nevertheless present, and can be demonstrated if the case is studied from the psychoanalytic point of view. I willingly admit that the prison milieu adds color to the psychosis, particularly a paranoid trend. The criminal is apt to regard himself as a martyr, and prison officials as hired bullies, and it is but an easy and natural step from this attitude to paranoid misinterpretations and delusion formation.

But even we who call ourselves normal are apt to project our difficulties upon our environment, or upon those about us, in lieu of acknowledging our own faultiness. So in a critical condition like imprisonment, it is but natural that the individual should interpret his misfortunes as the result of the malfeasance of others, rather than that of his own misdeeds.

To repeat, the fact that prison environment is able to produce a psychosis in an individual, indicates to my mind that he is of such a psychic make-up that any severe stress which affects his personal interests will produce regressive changes, a flight from reality manifested by some type of psychosis.

In discussing the place of the environment as an etiological factor in psychogenetic disorders, Pfister says, "In mental equilibrium, in suitable utilizatio nof the instincts and erotic demands, it should be noticed again that no external calamity, no stress of life conditions can bring about a serious repression." In another place he says, "The external calamity is a provocative agent, the light pressure on the button which shatters a mighty mass of rock." Again, "The external world only causes a repression where there was already present beforehand a strong internal tension—in this collision with reality we are dealing at bottom with an internal conflict." "Many maladies are nothing else than flight from a severe ethical conflict, many others represent expiations for past shortcomings, or counter-reactions to a burning feeling of shame." These opinions were expressed concerning the psychoneuroses in particular, but I believe that they are equally applicable to all psychogenetic disorders, especially the types known as situation-psychoses. That is to say, these psychoses represent flights from reality, escapes from painful situations and personal conflicts; they result from unsuccessful attempts at repression, in which the environment —in this instance the prison milieu—serves as a plausible excuse to the outer consciousness of the individual for giving up the attempt at repression or compensation. *The environment serves as a convenient medium through which to permit an easier transition from contact with reality and its unhappiness to a state in which this contact is severed, or at least obliterated sufficiently to permit escape from such conditions of reality as serve to remind the individual of his conflict.*

In the "prison psychosis" we are dealing with individuals who have had for longer or shorter periods the same types of internal conflict as Pfister describes as being at the base of the psychoneuroses. In these cases repression has been possible so long as the individual was free, so long as he was not subjected to too strong pressure from his environment.

Then there was added to the internal tension an extra demand upon his abilities an increased weight upon the already-present burden. Unable to react to this combination of factors, unwilling to face reality with its ever-present pain, there remains but one comfortable solution, flight or regression. The individual may project his difficulties upon those in his environment, with resulting persecutory ideas, he may seek lower psychological levels, or he may manifest his flight in other ways—but essentially, the symptoms he displays amount to a detachment from the discomforts represented by reality, and a seeking of comfort in a situation created for his relief.

As to the types of conflicts which underlie the psychosis, it is hardly necessary to go into details. As I have encountered them, they deal with the psychosexual life to a great extent. Unsuccessful efforts to reach the heterosexual level might be given as the essential expression of the nucleus of the trouble. In not a few cases a tendency to sexual perversion is present, frankly expressed, and the effort to subdue the tendency, or an expiation for the sinfulness of the desires is manifested in the internal conflict. The homosexual is very common among those who show this psychosis, and as noted above, the prison milieu brings to bear a very decided pressure upon these individuals. Among the prisoners are usually some frank homosexuals, and our patients may be approched by them. It is easy to imagine the effect that a homosexual approach has upon an individual who is struggling to repress these tendencies. In a case not quoted here, just such an occurrence helped to precipitate a psychosis in a boy who was struggling desperately against homosexual desires, and who had even withstood actual homosexual assault before being imprisoned.

When these individuals break down, they are usually removed to a psychiatric ward or insane hospital. The change of environment removes the factors which precipitated the psychosis, and the new environment in itself is beneficial. Provided that the individual has a certain amount of stability, he is able to readjust and form some sort of compensation. With the precipitating factor removed, there is no longer need for flight, which accounts for the sudden recoveries seen in these cases.

As I have previously said, the prison environment acts as the precipitating factor, and helps to color the psychosis. It adds the necessary weight to throw the delicately balanced psychic situation over onto the side of mental upset. But in these same individuals, any other equally strong affective injury would have the same effect. It is not the prison milieu alone which can produce the psychosis. Therefore, why should we continue to speak of "prison psychosis," as though it were due solely to the prison situation. If we must attach a name to the psychosis, let it be one which will indicate the personal factor as well as the environmental one. I have no suggestion as to what this name may be, for I do not care to add to the classifications with which psychiatry is already overburdened. My purpose is simply to call attention to the individual factors in these cases, to the part played by the patient's personal difficulties.

Having stated my own opinion in the matter, let me briefly state the opinions held by others. Dr. Bernard Glueck, in an article entitled "A Study of Psychogenesis in the Psychoses," concludes that there is a distinct type of psychosis due to the shock of arrest, trial, or imprisonment, which he designates as a defense reaction. He says that degenerative soil is not necessarily indicated by the development of this psychosis. He also concludes that the psychosis can not be classified as an attempt at malingering, and shows points of distinction between this psychosis and others which present similar phenomena.

In another article, Glueck asserts that the prison milieu is the etiological factor in these cases, and that "degenerative soil" is not a basic disorder, because of absence of progression of the psychosis to a definite end-result.

Bowers says, "The episodic psychotic symptoms which are exhibited in prison are but the kaleidoscopic picture of the criminal constitutionality which has been their heritage, or which they have acquired by evil environments, vicious habits, or low ideals during the formative period of the mind; the mental symptoms are merely evidence of underlying grave psychophysical pathology." While Bowers seems to have sensed the esential basis of this disorder, he has not stated his conception clearly, and seems to have based his conclusions on insecure theories and generalizations, rather than on practical grounds. For example, he states, "Recovery from mental disease among criminals is quite rare because their mental disorders develop on fertile and degenerative soil." This statement is not borne out by my own observations in the criminal department of St. Elizabeth's Hospital, nor by the observations of some of my associates who have had more experience than myself. I have seen recoveries among both recidivists, and those who were "criminals by chance" (the so-called "criminals as the result of passion"). It is rather a frequent occurrence in this institution to return to prison criminals who have recovered from mental disease, both of the episodic type, and of the more prolonged and characteristic types.

W. W. Richardson ends an article, "Imprisonment Psychoses," with the following conclusions:

1. The symptom-complex under discussion can not be regarded as a disease entity.

2. It develops most often in the adolescent or young criminal.

3. While it may complicate other psychoses, it very often occurs on a markedly defective basis, which in some cases amounts to imbecility.

4. It is not infrequently associated with evidences of an attempt at simulation.

5. While related to hysteria in nature, it can hardly be regarded as an hysterical psychosis, though of psychogenetic origin.

6. Great apprehensiveness, with partial stupor,

hallucinations of sight and hearing, and often mutism, are the most frequent symptoms. The rapid disappearance upon transference to a hospital for the insane is rapid and striking.

I agree with these conclusions in the main, but doubt that simulation plays a part as often as Richardson seems to think. Of course, simulation is often seen among prisoners, and even in this type of psychosis there is sometimes the added element of malingering, nevertheless in most cases where simulation is present, there will be found evidences of defective mental makeup.

Perhaps the most important recent contribution is that of Nitsche and Willmanns. After a thorough review of the history of the prison psychosis, considering them through three distinct periods, beginning with the first observations of Delbruck and Gutsch and their coworkers, through the period when they were studied in the light of Kraepelin's views, they discuss the Magnan-Moebius ideas of degeneracy, with their theories of predisposition, degenerative states and the like, with the views of Birnbaum, Willmanns, and others. In conclusion, they state that they believe "in suitably organized personalities, acute and chronic psychoses can develop, which may be placed alongside of those developing in free life in persons under the influence of strongly affective experiences. The peculiar symptomatology of these psychoses justifies us in considering them as special types, well differentiated from those developing in free life. A more exact knowledge of these psychoses would also permit gradually a greater accuracy in the limitation of smilar symptom-complexes which we frequently see as introductory phases of the juvenile demential processes."

Thus the better known authorities, such as Glueck and Willmanns, are inclined to believe that there is a definite symptom-complex, due to prison environment alone; one, however, states that it develops only in "suitably organized personalities," that is, with degenerative soil, while the other states that the development of such a psychosis does not necessarily indicate a defective soil.

I will not quote other authorities—in fact, the writings on this subject are chiefly confined to the Germans, and the German authorities are thoroughly reviewed in the work of Nitsche and Willmanns just mentioned. The conclusions reached by these writers seem to be those most generally agreed upon by the German writers.

I have stated my own opinion in the matter, and have briefly reviewed the opinions of others. I will now proceed to illustrate my opinion by five cases which have come under my observation. With the exception of the first case, all were admitted within a year and a half, and consist of two life-term prisoners, both murderers, a recidivist serving his second ten-year sentence, a five-year Army case who has returned to prison, and a sexual pervert, not a prisoner, but held here to protect the public on account of being considered a public menace. In one the psychosis has persisted, in two it cleared up before reaching the hospital, in another there is but a trace of the psychosis, and the last has been under observation only a few weeks.

The symptomatology involved is variable, but corresponds to the types of disease syndromes which has been described by various writers as belonging to the prison psychoses. Of just what this syndrome consists depends upon which authority one is to believe, as there is some variation in the descriptions given by different writers. However, this is unimportant so far as it concerns the present article. I have selected cases in which the most apparent cause of the mental upset was prison confinement, and attempted to discover some deeper underlying cause. The cases are treated from the psychoanalytic standpoint, though none of them have been psychoanalyzed. Perhaps I may be criticized as having apparently jumped at conclusions in my interpretations, but I believe that I have been justified in them, and have no apologies to make.

Case I.—M. C., a colored man, thirty years of age, a barber, having a public school education, was sent here from Leavenworth Penitentiary, where he was serving a life sentence for murder, having stabbed a colored man at a picnic. He was sent here because ot erratic conduct, delusions of grandeur and bizarre ideas. On admission he was orderly, polite, talked freely, but was slightly retarded in speech and actions. In giving his life story he freely interpolated his delusional ideas. Prominent among his delusions was the idea that he was a white man, but had been painted black by his father in a scheme to recover a large sum of money which he owned, but did not have in his possession. Auditory hallucinations were present, the voices making "sissy remarks" and cracking jokes. By "sissy remarks" he meant references to homosexual acts. Later the patient said that his victim was not dead, merely shamming, so that he was not guilty of a crime. There were many other bizarre ideas, which need not be described here. He was in poor contact with reality and talked in a vague, rambling manner. At first he was somewhat depressed, and showed some mannerisms. His dreams related to his delusional ideas. He was poorly oriented for time, was somewhat distractible, but performed the intelligence tests well.

During the years that followed his admission he has conducted himself well, has been an efficient worker, and of late has done some clever woodcarving with a penknife and piece of broken glass. He remains quite delusional. While many of his delusions are changeable, he has consistently retained the idea that he is a white man of wealth, educated, and a big contractor. He often implores the physicians to have the paint removed, that he may show that he is a white man, and obtain his freedom and money.

Superficially he makes a very good appearance. He is in fair touch with reality, in so far as it does not conflict with his comfort—before this contact reaches the painful point, his phantasies interfere. He has auditory hallucinations, and persecutory delusions, to which he does not react. In his first years he wrote many letters to prominent officials about his case, but of late has given this up and turned his attention to woodcarving and other constructive work.

Here we have a psychosis which developed in prison, when the patient had before him the prospect of a life sentence. He developed a mechanism (or psychic situation) in which he is a white man of wealth and position, innocent of the crime because his victim still lived. This he elaborated somewhat, so that he is always expecting to secure his release and enjoy the comforts of which he has been deprived of by the persecutions of others. The whole constitutes a situation which is bearable because it lifts him out of the realm of cold reality. This would seem, at first sight, a sufficiently complete explanation.

But let us inquire further into this case, studying it from the psychosexual side. The reader will ask, "Where can there be any connection be-

tween the man's sexual life and a psychosis developed in prison?" In answer, I present the result of further study of the case. The patient is frank and accessible for the most part, but had to overcome considerable resistance in speaking of his sexual life. Even then he could not bring himself to discuss the details. He has a tendency to incorporate into his account of his life some of his delusional ideas, and is slightly deteriorated.

I will omit the detailed study of his sexual life, and summarize the findings as they appeared at the end of the study. The man had passed through the usual period of onanism, and his psychosexual development had ceased at the homosexual level. On a few occasions he had participated in homosexual acts, but he was one of the better class of his race, and his moral scruples would not allow him to continue these practices. As is the case in so many other homosexual conflicts, he compensated in part for the suppression of his abnormal desires by the use of alcohol. Heterosexual congress, on the few occasions practised, was quite unsatisfactory, and he was at times heterosexually impotent.

Here, then, we have a different picture—a youth striving unsuccessfully to adjust his psychosexual life; having reached the homosexual level and being unable to attain the heterosexual level. While so struggling, he met a woman, who later turned out to be the wife of a friend. He carried on an affair with her for a short time, and then, discovering her identity, broke off the affair because of the loyalty to his friend. He had perhaps begun to make a successful heterosexual adjustment, with this woman as the instrument, when his desire for her conflicted with the conventional idea "Thou shalt not covet thy neighbor's wife." In this state of mind, he attended the picnic, and the husband's jealousy led to a fight. We do not know the details, but it is quite safe to assume that the fight was the world-old struggle for the possession of the sexual object—a primitive conflict in which the victor took the woman as his own by right of conquest.

Unfortunately for our patient, our modern laws do not recognize the right to kill one's rival in love, and said that he must spend the rest of his life behind prison bars. Prison life, with its homosexual environment, meant the renewal of the inner conflict—brought to bear added pressure against his effort to repress his homosexual desires. Combining this conflict with the prospect of life imprisonment. and the result was an exceedingly painful situation.

Another feature of his delusions as developed in the resulting psychosis, was the idea that he was persecuted by the attentions of homosexuals because he would not submit to their desires. This is a typical defense mechanism of the homosexual individual, and always denotes a reaction to a homosexual conflict.

The situation outlined above could only be met comfortably by the construction of a mechanism which would free him from the guilt of his crime, and make him a superior type of man. So the series of ideas given above were developed, and as the years passed, and he had no prospect of freedom, or of release from homosexual environments (for the institutional milieu is also homosexual), these ideas became a part of his personality. Retrospective falsification of memory has helped to fix the convictions of these things more firmly in the content of consciousness. For example, he states that he remembers being a white man until he was 39 years old, that he was a contractor and an influential man. Then it became necessary, on account of the persecutions of homosexuals, who would permit him no freedom, no intercourse with women, etc., to disguise himself as a negro, and spend a certain number of years in prison to escape them.

With such a mechanism he continues to live in a comfortable atmosphere, one from which is excluded everything which is painful; taking to himself that which is satisfying, excluding that which calls for painful adjustment. He maintains a partial connection with reality, enough to admit all comfortable stimuli, but not those which would mean discomfort. The flight, however, is not only from the prison situation, but fully as much from the homosexual conflict, the effort to adjust the psychosexual conflict. As such, the mechanism is typical of inversion. We do not know anything about the patient's mental state previous to arrest and imprisonment, but he at least had adjusted well enough so that there was no suspicion of mental trouble until after he was imprisoned. Apparently he had been able to make some kind of compensation, but with imprisonment, the possibility of compensation was lost, there was no comfortable outlet for the libido. Therefore he took flight into a phantasy world, where, with himself as the central figure of his little universe, he is able to lead a comfortable existence.

To those opposed to Freud's theories, the explanation that the patient's psychosis was a defense mechanism against the uncomfortable prison milieu is all-sufficient. To those who can look deeper into the case, the underlying factor is the man's desperate struggle for adjustment of his psychosexual life, a struggle in which he might have been the victor, had there not been added to his burdens the extra and heavy factor of life-imprisonment, and the constant homosexual environment. The prison milieu was the *precipitating* factor, but the internal conflict was the basic one, and I am unable to understand why we should call this a "prison-psychosis," and neglect the individual factors in the case.

Case II.—J. P., a white man of thirty-five, began life under serious handicaps. The youngest child of a large family in poor circumstances, his childhood was darkened by the influence of a drunken, brutal father, who forced upon the boy at a tender age the use of alcohol and tobacco. The father was in the habit of getting the boy drunk in order to be amused by his actions when in this condition. He beat and abused the boy and his mother, as well as the other children. Many times the boy was forced to leave home and live with a married sister. His school life was irregular, as he ran wild with a gang and was a frequent truant. He practised onanism in early boyhood and has never freed himself from the habit. At fifteen his brother's wife, a woman of loose morals, seduced him, and he was intimate with her for several years. He despised her and at the same time fell in love with her daughter, whom he could not, of course marry, as she was his niece. She exercised a considerable influence upon his life. At twenty-two, feeling the hopelessnss of his love for her, he attempted, while drunk, to kill her and commit suicide. She recovered, and he served

about seven years of a ten-year sentence. After his release he traveled about, working at odd jobs, but within six months was again arrested when he tried to hold up a restaurant keeper, and received a second ten-year sentence, which he is now serving.

About three years after beginning the second sentence, he began to show marked depression, was pantophobic, had delusions of persecution, auditory hallucinations, and attempted suicide. He had given information which prevented the escape of a number of prisoners, and heard the other prisoners calling him a sneak, stool-pigeon, degenerate, etc. His heart-beats seemed to be confessing all his life sins. He felt afraid of everything in his environment. His persecutory ideas disappeared before reaching St. Elizabeth's, and he showed only a few residuals of his psychosis, most notable being a lack of insight into certain of his delusional experiences, which were no longer present, but well remembered.

Here we have, in a recidivist, a brief psychosis marked by depression, suicidal attempts, pantophobia, persecutory ideas, and auditory hallucinations, which cleared up rapidly upon his removal from prison. Apparently the psychosis may be easily due to prison environment. But the man had successfully weathered a previous confinement, and while the prison officials are said to have considered him peculiar during the three years preceding the onset of frank psychotic symptoms, he apparently had managed to make a fairly normal adjustment to his environment.

A careful inquiry into his sexual life reveals the fact that he has been a life-long onanist. His heterosexual experiences have been few, and admittedly unsatisfying. Toward the latter part of his first prison sentence, strong homosexual desires began to manifest themselves, and were, for a time given free play. On his second admission to prison the same condition held for a time, to be followed by an intense psychic conflict. He had to constantly suppress these desires, and to one of his make-up, sublimation was impossible.

The only comfortable solution, and the most natural one under the circumstances, was a projection of his difficulties onto those in his environment, as manifested by the persecutory ideas and pantophobia. This was favored by the fact that he was for the time unpopular with the other prisoners, because of having prevented an escape. Even this projection was not sufficient, and the depression was in part, at least, due to the fact that he considered himself a hopeless degenerate. The suicidal attempt was a symbolic self-crucifixion, *often seen in this type of case*, and was rather superficial.

The exact mechanism of this case can not be worked out at this time. However, certain points are obvious to those versed in Freudian literature. The man has always been of latent homosexual makeup, and his difficulties were not far from the surface. They were poorly sublimated, and his chronic alcoholism was in all probability a compensatory measure. Prison life, with its homosexual environment, brought to bear such a pressure that compensation finally became impossible, and for a time the moral censorship relaxed, and his desires were frankly indulged. But not for long, for the psyche renewed its efforts at repression, and his temporary freedom between the two sentences made the repression possible for a time. With renewal of the homosexual milieu in his second prison term, the conflict was again renewed, and while he succeeded from refraining in indulging his desires, the conflict became too great to be successfully carried on without an escape from reality. As has been explained, most of his difficulties were projected upon his environment, and he regarded his depression as being due to worry over a sick relative.

Another factor was present, a strong mother-attachment; also a probable incest complex involving his sister-in-law and niece. In all probability, behind this complex lay a substitution of the mother-image, the niece and sister-in-law symbolizing the mother-image. However, in this almost illiterate individual, with rather defective intelligence, the exact working out of these factors is impossible.

I believe, however, that I have demonstrated that the basis of the psychosis lay in the life-long internal conflict, and that the prison milieu sufficed to precipitate the psychosis and add color to it. The psychosis was a flight from a reality which was far too painful to permit of anything like a comfortable existence. Removed from the prison environment, he was removed from the extra pressure on the conflict, and was therefore able to repress the internal struggle and adjust to his new environment. He has been under observation only a few weeks, so that the future of his case can not be prophesied. However, being a defective individual, with such an intense internal struggle, and the prospect of several years of confinement, the outlook is not promising.

Case III.—A. R., a young man of twenty-three, admitted July 11, 1917, while serving sentence for a charge of sodomy. He was the son of a prosperous plumber, and early in life showed an inclination for study, but in lieu of following any special bent, read widely on various scientific and philosophical topics. He remained at home until eighteen years of age. Of his home life he would tell but little, claiming that it was happy. He did not enjoy the games of other boys and was somewhat seclusive in habits. From the age of ten to sixteen he used to indulge in day dreams about every girl he met. At fourteen he began to masturbate, and ceased at sixteen when heterosexual life began.

At eighteen he decided that he must "strike out and make a man of himself," and decided upon the Army as a career. He accordingly enlisted, and transferred to different organizations on two occasions. He bought out his first enlistment in thirteen months, and had served less than a year of his second enlistment when he was court martialed and sent to Fort Leavenworth. Previous to the offense for which he was tried he had a good record, and was considered to be an exceptionally capable stenographer and typewriter. The charge on which he was tried was that of sodomy and the evidence seems to have been conclusive, as he received the maximum sentence.

According to the patient's story, on account of his superior education and lack of desire for drinking and carousing he did not mingle much with his fellow soldiers, and was therefore considered a snob. On one occasion a comrade was visiting him in his room, while the rest of the company were drinking outside. Two of them knocked at his door and asked who was inside. Receiving the joking reply "Find out for yourself," the visitors went back to the drinking soldiers and said something was wrong. The patient and his visitor then joined the crowd, and one of them accused the two of sodomy. His friend became frightened and reported the matter to his superior. As a result, both were tried on the charge of sodomy. The friend plead guilty. The patient held out for a time, but although innocent, was persuaded by his counsel to plead guilty, on a promise that he would merely be discharged from the Army and not imprisoned. To his surprise, he was sentenced to five years in the penitentiary.

On his arrival at the prison it was soon noted that

the prisoner was of extremely effeminate make-up. Nearly a year later he was placed under mental observation because he was acting hysterically, was emotional, excitable, had wandering delusions, showed a tendency to distractibility of attention, and made open, unashamed homosexual advances to the attendants. He threatened suicide on several occasions, but made no attempts to carry out his threats.

After six months' observation, with no tendency to improvement, he was sent to this institution. On arrival none of the above-mentioned symptoms were present. His physical make-up and manner were decidedly effeminate, but no evidence of frank homosexuality was manifest during our observation of him.

For the episodes in prison he was totally amnesic, although his memory was excellent for the other parts of his life. In the discussion of his sexual life he immediately launched into a long discussion, the purpose of which was to prove to the examiner that he was strongly heterosexual. He claimed to have had a common-law wife for three years, and told, with an element of boastfulness, of having contracted syphilis at one time. It was evident that he understood the nature of the sexual perversions well and had also read textbooks on psychiatry. He claimed that he was of somewhat eccentric make-up, and this, combined with his tendency to read abstruse books and avoid the society of others, might lead people to believe that he was mentally unsound. In an effort to bring out any homosexual tendencies he absolutely denied them, and neatly avoided giving expression to any idea which might be regarded as pathological. To even an inexperienced observer, however, the man was of undoubted homosexual make-up.

His features were effeminate, and this was accentuated by parting the hair primly in the middle. Speech was feminine, words were precisely formed, and he used such expressions as "goodness me," "oh, my," etc. He seemed rather anxious to demonstrate his studious disposition and was always seen with a book in his hand, reading some work as "Critique of Pure Reason," "Dogmatic Theology," "Fourth Dimension," etc. He had written a number of poems, showing no great originality, and in at least one of them homosexual symbolism was present. He also had a list of some forty scientific subjects of which he claimed to have knowledge. He was at all times anxious to demonstrate his masculinity and steadfastly refused to comprehend why anyone should think him homosexual. He had a somewhat exalted opinion of his scholastic ability, which he hid under a veil of pseudo-modesty. Close observation failed to reveal any real pathological material in his case and he was returned to prison four months after admission.

On account of his lack of any real frankness, no analysis of his case was possible. To my own mind, however, the case is fairly clear. If we can afford to omit the study of his childhood, and the influences surrounding him during that period, we find the following picture:

A home-loving, studious, pampered boy lives a protected life until 18. He shows little tendency to develop his abilities in any direction. At 18, he suddenly decides that he must strike out for himself, and demonstrate his fitness to cope with the world. Such a decision can mean but one thing in a boy of his make-up. It is purely an attempt to satisfy himself of his masculinity and potency. Quite in keeping with this is his choice of a vocation—the Army, symbolic of virility, aggressiveness, and all the masculine qualities. That he did not find this a comfortable situation is shown by his two changes of organization, and the buying out of his first enlistment. Army life meant a homosexual environment, with a strong pressure brought to bear on the man's repressing forces. What actually happened to cause his arrest we do not know, nor is it of importance as to whether he did or did not commit the act with which he was charged. Of decided homosexual make-up, his knowledge of sexual matters enabled him to make a superficial sublimation, manifested by overzealousness in study.

When thrown into prison, however, the situation was more than he could comfortably handle. The repression no longer held, and, as a path of least resistance he fled into a psychosis, separated himself from reality, and, what is more significant, permitted his homosexuality free play during the period when the psyche no longer exercised the repressing function. As long as he was in the prison environment, the same pressure of the homosexual milieu was present, besides the loss of freedom and the shame of his trial. Removed to another environment, he showed the sudden return to normal so often manifested in these psychoses.

However, in this readjustment, to eliminate such painful effects as the knowledge of his condition during his psychosis might have produced (especially referring to the homosexual outbreaks), it was necessary that there should be an amnesia for this period. This forgetting of unpleasant things is a normal mechanism of the psyche; were it not for the ability to force them back into the unconscious, there could be no comfortable adjustment to the environment, no refinement or sublimation of the libido, with its direction into useful channels.

The symptom-complex which this man manifested in prison corresponds nicely to the prison psychosis. The simplest explanation, of course, is that it was a defence-reaction against the painful situation created by imprisonment. The man had previously made a fairly good adjustment to his environment, but there had always been the internal conflict; the Army proved a situation to which he adapted poorly, and the prison milieu sufficed to act as a precipitating factor. The man's boast of Don Juan-like tendencies is a common type of defense reaction in homosexuals, an attempt to convince themselves and the world of their heterosexuality. And the present patient intends to marry when he is set free—which is of course only another attempt to test his heterosexuality.

While the prison milieu precipitated the psychosis, underlying it was a life-long internal conflict, which was the real basis of his inability to cope with the imprisonment situation.

Case IV.—J. W., a Manomini Indian, of a fair education, serving a life sentence for murder. Soon after entering prison he developed poorly systematized delusions of persecution with reference to a guard and several fellow-prisoners. He was much distressed for a time with the idea that poisonous powders were blown on him during sleep, rattlesnake oil put in his ear, etc. On admission to Saint Elizabeth's he repeated the same ideas. He has been under observation only a few weeks, so that the study of his case is necessarily brief. He is pleasant, accessible, slightly depressed, but at the same time quite satisfied with himself.

His history shows that he was the fourth child of a well-to-do Indian family, attained a grammar school education without difficulty, and learned the carpenter's trade. He worked at various occupations, and was an enthusiastic and successful hunter and trapper, with his racial instincts little influenced by civilization's veneer. At twenty he met a woman of his own race, of the same age, with whom he became friendly, though he did not love her. According to a custom of their tribe, their parents arranged a marriage, and he was practically forced into the union against his will. During a married life of ten years two children were born to them. They were not happy—he felt she was not his equal in education, and they were sexually incom-

patible. She was frigid, except just after the menses, and he never obtained true enjoyment from intercourse. Also she refused to permit coitus at times. After ten years of unhappiness he deserted her, and she obtained a divorce and remarried. He then patronized prostitutes occasionally, until he met a beautiful and accomplished Indian girl ten years his junior. The attraction was mutual and they were sexually intimate for a time, with both equally enjoying coitus. The girl's parents broke up the affair after a child had been born to them.

The patient then began to indulge heavily in alcohol—a new thing for him to do. After two years of hard drinking, he returned to the girl's home, shot her dead, and unsuccessfully attempted suicide. As a result he was given a life sentence in Leavenworth. In his account of the murder he shows a partial amnesia, combined with a tendency to falsification of memory, which makes the recollections less painful.. As stated above, after imprisonment he began to develop delusions of persecution relating to people in his environment.

We do not know what the outcome of the psychosis will be, nor can the patient cooperate in the analysis. However, my explanation of the mechanisms present is this: The man has a strong mother-attachment. He states he always liked his mother best, though he does not know why. In his dreams the mother appears often, and often in plainly symbolic relation to the patient. He often dreams of seeing snakes while walking with his mother, and of killing snakes when she is present. This needs no interpretation for those versed in psychoanalytic literature.

In his marriage, the wife did not meet the requirements of a mother-substitute, and was therefore a failure. The paramour, on the other hand, seems to have made an excellent mother-substitute, and his relations with her were very happy. When he lost her, he reacted by over-indulgence in alcohol, which almost always means a drowning out of complexes, a temporary and easy means of escaping from painful conflicts. Brooding over the loss of the one mother-substitute, knowing he could not have her, jealously forbidding that any one else should possess her, he resorts to extremes, as shown by his crime. Thrown into prison, his internal conflict as active as ever, this freedom-loving savage is deprived of liberty, has the prospect of a life-imprisonment, and no comfortable means of sublimating and at the same time maintaining in proper contact with reality. He sought peace by projecting his difficulties upon his environment, making himself a martyr, his associates the guilty ones. From the situation created by the psyche he is enabled to exist comfortably. The prison confinement acted as a precipitating factor, when added to a struggle which had influenced the patient's whole life. The mother-complex was the underlying influence, the prison-situation merely coloring the psychosis, and serving as sufficient weight to overbalance the psychic struggle and permit a flight from reality.

Case V.—F. G., an American of twenty-five, was arrested for a perverted sexual assault on a child. Shortly after his arrest the man became confused, was apparently of low mentality, and showed a catatonic-like state. When he arrived at St. Elizabeth's, however, he showed no trace of a psychosis, intelligence was found to be normal, he was friendly in attitude, and reacted well to his environment.

Family history shows that his mother had a brief mental upset at the time of her marriage. As the mother and brother have been observed on their visits to the patient, they are rather eccentric and consequently refuse to see that the patient has done anything wrong or that he should be kept here. They are rather paranoid in attitude as regards the institution and its officials.

The patient's past life shows nothing of interest before his seventeenth year. He was an average student and received a fair education. Home life was happy, and his relations to relatives and friends were normal. He was fond of athletics, but somewhat seclusive in habits. By his neighbors and friends he had always been considered a model young man. However, we find that he was discharged from a position as street car conductor because of failing to register fares properly.

The details of his sex life will not be given here. Suffice it to say that he has practiced cunnilinguis since the beginning of his sexual activities, and has always been quite impotent in every other type of sexual indulgence. His desires have always been given free play, and he had no difficulty in keeping his peculiarities from being known to his associates until the abolition of the red-light district. Thereafter he could seldom find an object for his indulgence and began to experience considerable mental distress. On one or two occasions his impulses led him into trouble, and his present prison confinement is due to the fact that he attempted to assault a child in a public park and was discovered. He states that the shame of arrest and the realization that his friends would now become acquainted with his abnormality made him lose control of his mental balance for a time. He fully realizes that he is different from other men and has made a number of unsuccessful attempts to live a normal sex life.

Leaving out the sexual factors in the case, the psychotic episode corresponds nicely to a prison psychosis. But this sexual pervert is not normal, even if we set aside the perversion itself. He is seclusive, dishonest, impulsive, and there is a constant internal conflict, a battle between his desires and his moral code. His desires conflicted with his wish to conform to the social standards, for they were considered wrong by those in his environment; as Pfister says, the individual must accept the social morality standards as his own, as the voice of his consciousness, before there can be any conflict between his repressed desires and his environment. In this case, the patient opposed to his desires the voice of consciousness which told him they were wrong, because they were not approved by social standards, therefore conflicted with his environment. After each indulgence, he felt remorseful, and the internal conflict grew more intense. But since he had been able to hide his short-comings from those in his environment, and was not of unstable make-up, there had been no need to withdraw from reality, as the conflict had not been sufficiently severe to require this. In the prison situation, however, he faced the prospect of trial, imprisonment, and disgrace, a conflict with his environment which could be avoided in only one way—flight into a psychosis. While the patient was in this state of flight, he learned that his relatives were to have him sent here to avoid trial; the necessity for flight being removed, he regained his normal state.

The internal conflict remains, however, and that it is far from being successfully sublimated was recently shown in a cunning attempt of the patient to secure the undergarments of a young girl whose name he chanced to read in the paper. But for the timely interception of a smuggled letter by a relative of the girl, he might have secured the garment. The details of his scheme need not be given here, but they showed an uncommon shrewdness on his part. It is noteworthy that he showed no shame when questioned about the incident.

The question of simulation might be considered in this case, but I believe that there is little doubt but that the patient's upset was real. And according to the most recent beliefs, malingering or simulation is, in itself, evidence of psychopathic make-up, and no normal man ever simulates disease of the mind.

In this case, then, the imprisonment served as the precipitating factor in a conflict which had heretofore been successfully repressed—and which is still present, though the psychotic episode has cleared up.

THE POSSIBLE SPREAD OF INFLUENZA THROUGH THE BEDBUG.

By G. A. FRIEDMAN, M.D.,

NEW YORK.

It is generally understood that influenza, like measles, spreads from person to person, and it is also assumed that were it possible to isolate the first case of influenza in a community epidemics or pandemics of this disease would not occur. Until recent years the same conception was maintained by the profession regarding typhus fever. However, the etiology of typhus appears established now.

Prior to the isolation of the *Bacillus typhi exanthematico* by Harry Plotz, Nicolle[1] and his associates, Anderson and Goldberger,[2] independently, as well as Rickets and Wilder,[3] have shown that the body louse is the transmitting agent of the virus of typhus. Rickets and Wilder excluded the flea from serious consideration because the season during which this insect is most abundant did not coincide with the greatest prevalence of typhus. Their personal observations further proved to them that the bedbug was not the carrier of typhus. These authors, too, have studied Rocky Mountain spotted fever, a disease which has a great deal in common with typhus, and have shown that spotted fever is not contagious, but is transmitted by the bites of a certain species of ticks, so that the presence or absence of this variety of insects determines the state of the disease in any locality.

Is it not plausible, then, that the influenza virus is transmitted from person to person by an insect? Insect transmission being admitted possible, the bedbug, in all probability, is the carrier.

A few preliminary remarks are essential. It seems that the present epidemic did not bring us a step further in establishing the Pfeiffer bacillus as the etiological factor of influenza. Thus our stand in regard to the causative agent of this disease is still uncertain. Assuming as correct, therefore, that the specific organism has not been discovered so far, the investigator who seeks to determine the cause of influenza should proceed along the lines of research similar to those leading to the etiological factor in typhus and search for an insect as a transmitting agent.

Insect transmission in influenza may seem at the first impression startling and absurd, as we are accustomed to regard influenza as primarily and essentially affecting the respiratory tract. However, during the present epidemic there was obtained sufficient evidence that the disease may also attack primarily the gastrointestinal tract. Thus cases were observed in which, in addition to the respiratory disturbances, an upset in the gastrointestinal tract was evident. Cases were also noted by the majority of physicians in which vomiting, diarrhea, severe abdominal pain, or a combination of the three, was present without the slightest affection of the respiratory tract, even after the most careful search for physical signs in the chest. Were such cases observed before the acute stage of the epidemic, or sporadically, they would never have been diagnosed correctly as influenza. The high fever, chills, and sweats which accompanied the gastrointestinal symptoms, the previous or simultaneous occurrence of influenzal pneumonia among members of the same family, the presence of an epidemic, make the diagnosis of the gastrointestinal type certain.

In the afternoon of October 28, 1918, I was called to see W. M., female, aged twenty-one years. Her complaints were fever, sweats, diarrhea, and severe abdominal pains which began on the evening of October 22. During the morning of the same day when she was first seized with her illness she received her third vaccination for influenza. The first vaccination was given to her three and one-half weeks previously; the second, one week after the first. On examination I was unable to detect physical signs in the lungs, nor were there signs of rhinitis, laryngitis, tracheitis, or conjunctivitis. Marked tenderness in the upper abdomen, with rigidity of both recti, was elicited. The rectal temperature was 103.5° F. On further questioning, I learned that her brother, who did not receive preventive vaccine, was convalescing from an attack of influenza which, judging from the history, was of the respiratory type.

Such and similar cases must shake one's belief that influenza is a disease in which the first line of attack is the respiratory tract.

Typhus, as I have seen the disease in Russia, also affects the respiratory tract at the onset, and still no one will claim, with our present knowledge, that in typhus the organs of respiration are those which primarily become affected with the typhus virus.

In a paper published in 1911,[5] in which I discussed sporadic typhus as it occurred for years in New York City, and which was commonly known as Brill's disease, I stated that in countries where sporadic typhus is common it is frequently confounded with influenza in adults and with measles in children, because of the respiratory disturbances common in typhus as well as in measles. I now find a corroboration of my statement made seven years ago in a recent paper of Hitzig,[6] whose observations on the Mexican typhus correspond to those on the European typhus. A further fact in support of the assumption that in influenza as well as in typhus the first appearance of the virus occurs in the blood stream may be surmised from the following consideration: If any one makes a comparison between the toxemias seen in the present epidemic with the toxemias observed in severe typhus, the conviction must be forced upon him

that influenza, like typhus, must be essentially a blood infection, and not a primary respiratory infection.

It is true, however, that typhus fever has no demonstrable pathology; still, the pneumonia following or or occurring simultaneously with influenza had a great deal of pathology, especially in the recent epidemic. The unusual pathological changes found in the lungs led Symmers[7] to recognize a similarity of the pulmonary changes in influenza with those observed in bubonic plague. There is difficulty in ascertaining whether in any of the previous epidemics of influenza similar changes were observed in the lung tissue, or if the toxemia was so marked, but Graves[8] mentions that the second and third stages of ordinary pneumonia were almost always absent at necropsies in the epidemic which came under his observation. But all have observed in the last epidemic the severity of the toxemia. In many of the patients the toxemia was so severe that some died on the second or third day after the onset. The first patient whom I saw during this epidemic was a young Turk, admitted to my service at the Beth David Hospital. So severe was the toxemia that on inspection he impressed me as a man in the algid stage of cholera such as I have often seen during epidemics of the disease in Russia. M. Roux states that blood cultures exhibited streptococci of exceptional virulence in the influenza patients and that a local doctor accidentally inoculated by the streptococci died in a few days showing grave symptoms against which all remedies proved powerless.

Since, in the course of typhus, pneumonias with the unusual pathology noted in influenza hardly ever occurred, one must assume that streptococci and pneumococci, in the presence of a highly virulent influenza microorganism, are liable to cause the peculiar lung changes. But this would merely mean that the typhus bacillus which first enters into the circulation is not apt to enhance the pathogenicity or virulence of the pneumococcus or streptococcus.

After the analogy of typhus, in which the infection occurs through the medium of the body louse, we must now look to the carrier of influenza, which I believe to be the bedbug.

The transmission of influenza by an insect must be in accord with the chief features of the epidemiology of the disease. (1) The insect must be able to exist in all seasons of the year. (2) It must be able to gain access to rich homes as well as to dwellings of the poor. (3) It must retain the highly virulent microorganism for a limited time, approximately corresponding to the duration of the acute stage of the epidemic.

Unlike typhus epidemics which occur almost exclusively in the winter, or cold, months of the season, epidemics of influenza, while occurring mainly in the spring, summer, and autumn, appear also in the winter. Bedbugs which live exclusively on human blood hibernate, according to Chandler,[9] in a semitorpid condition in cold weather. In warm climates they are active the entire year. Bacot[11] states that unfed, newly hatched bugs are able to withstand cold between 28° F. and 32° F. for as much as eighteen days, though they are destroyed by exposure to damp cold after a full meal. Dufour[12] kept bedbugs alive and active for a year in a tight box without any food at all. I remember well spending two sleepless nights on account of bedbugs in a Russian hotel during a cold December.

Contrary to typhus, which is a disease almost exclusively of the poorer classes, and rarely affects the well-to-do, even during epidemics, influenza does not spare the wealthy or even those residing in palaces. The insect, therefore, must be one that has access to good homes as well as poor.

There is no need to dwell upon the fact that bedbugs are almost always present in the dwellings of the poorer classes, and it must be also admitted that bedbugs in good homes are frequently beyond the control of the best housekeeper. They may be brought in with the laundry or in clothes of servants. Herrick[13] states that he has often seen them hiding away in the crevices of clothes baskets. In several instances he has seen the insects on the white spread of the bed on which the clothes have been laid by the laundress. This he believes is a source of infection that has to be constantly watched.

It is believed by some people that the iron bedstead, which has so rapidly replaced the wooden ones, has done away with the bedbugs. This is a mistake. Bugs, according to Shipley,[14] will shelter themselves in the metallic crevices of the iron bedstead almost as comfortably as in the wooden chinks of its predecessors.

The next route by which the bedbugs may enter a home is through hotels. The more often members of a family travel and stop at hotels the more liable are they to bring the vermin home in their trunks, handbags, or clothing.

In towns and cities where houses are built closely together the bedbugs will migrate from one house to another along the walls and pipes. This is especially liable to happen where one house has been vacant for some time and the parasites have been deprived of food. Marlatt[15] says that the insect will continue to come from one house to another sometimes for a period of several months, gaining entrance daily.

The bedbug is particularly common on ships, sleeper berths, and cars, especially in the plush seats of the railroad coaches. Bedbugs may also be present in any place where there is an accumulation of dirt, on the battlefield and in trenches.

It is evident that in normal times bedbugs frequently accompany traveling men from ship, trains, hotels, etc., in their baggage. At times these bugs may be the carriers of an attenuated influenza virus. At other times, when favorable conditions exist in a certain locality, as perhaps has occurred at the present time on account of war conditions, during which Pfeiffer's bacillus must have found an excellent cultural medium on the dead bodies of the war victims, the supposed microorganisms gained in virulence.

Insects carrying this extremely virulent bacillus may have found their way from all the battlefields by means of ships, railroads, hotels, etc., and finally gained access to the tenement houses as well as to the apartments of the rich.

Thus there is apparently little surprise at the information of Dr. Harris[16] about the origin of the influenza epidemic in New York City. Harris

states: "On August 11, 1918, we were informed by the quarantine officers that a Norwegian steamer had arrived in this port giving a rather interesting history. We found upon investigation that during the voyage two hundred passengers had become ill with influenza."

There is surely a carrying agent for the causation of the disease, air dissemination being insufficient. One must assume from the above considerations that some of the passengers introduced the disease, carrying the germs in their luggage. Since bedbugs are often present on ships, they must have been the carriers of the influenza virus. In the histories of influenza epidemics there are sufficient instances proving that outbreaks of the disease occurred on ships which did not come near the shore at any time while influenza prevailed on board.

The following report is found in the records of the College of Physicians[17] on the epidemic of 1782: "On the second of May, 1782, the late Admiral Kempenfelt sailed from Spithead with a squadron of ships under his command, of which the *Goliah* was one, whose crew was attacked with the influenza on the 29th of that month; the rest were affected at different times, and so many of the men were rendered incapable of duty by this prevailing sickness that the whole squadron was obliged to return to port the second week in June, not having had communication with any shore, and having cruised between Brest and the Lizard." The insects evidently only became active twenty-seven days after sailing. Another instance shows that "about the sixth of May Lord Howe sailed for the Dutch coast with a large fleet under his command; all were in perfect health. Toward the end of May the disorder first appeared on the *Rippon*, and two days later on the *Princess Amelia*. Aboard other ships in the same fleet the men were afflicted with the disease at different periods, some, indeed, not until their return to Portsmouth about the second week in June. This fleet also had no communication with the shore until their return to the Downs on their way back to Portsmouth, toward the 3d or 4th of June."

The following narrative of Gray[18] is very interesting: "Among the islands on the western coast of Scotland there is one very remote from the rest, named St. Kilda. It rises like a rock in the ocean, about 16 or 18 leagues west of the Lewes Islands. The place is inhabited by twenty or thirty poor families, who subsist chiefly on the flesh and eggs of sea fowl which they have in prodigious quantities. They have besides a small amount of barley and a considerable number of sheep. The open and boisterous sea around them, together with their distance from every other land, exclude these poor islanders from the rest of their species; and they scarcely ever see a human being besides themselves, except once a year when they are visited by the steward, who receives the rent in feathers, wool, and mutton.

St. Kilda being an appendage to that part of Lewes called Harris, and the property of Mr. Macleod, the steward always resides in the latter place. He makes his annual voyage to St. Kilda in the month of June, when the day is longest and the season most temperate. His retinue consists of ten or a dozen men, sufficient to manage a large open boat such as are in common use in the islands. The inhabitants meet him on the beach, and, prompted by a desire of intelligence as well as respect for his person, all assemble around the stranger. But behold the consequence. The next day the steward has hardly a St. Kilda man at his levee. They are universally seized with a catarrh or cold, as they call it, which rages so fast that in twenty-four hours every individual on the island is generally laid by. The symptoms are a cough, headache, sneezing, and coryza, from which they recover in a few days after drinking largely of water gruel and other diluting liquors that promote perspiration. This is so invariably the case that it is considered as the natural and infallible consequence of the steward's visit, and the poor people are prepared accordingly. I remember Dr. Cullen mentioned this circumstance in his lecture on catarrh about six years ago, when I attended him, but I have had still better opportunities of knowing the matter in its full extent than the doctor, and connections in that part of the country enable me to give it on the strongest grounds of authenticity."

Since bedbugs are commonly found in hotels, the following instance may serve as an illustration:[19] "Very early in June three families, consisting of seventeen persons, came on the same day to the Adelphi Building of London; they were all in the best of health when they arrived, but the next day all were affected with the symptoms of influenza, then raging in London."

There is also a positive case where the disease was communicated through the medium of clothes. Edgeworth[20] tells us that the influenza in 1803 "was brought from Dublin to London by a parcel which was made up by a person very ill of that disorder and sent to a lady of quality here. As soon as the parcel was unpacked the person who unpacked it was the first seized, then the lady herself, the rest of the family next, and finally the neighborhood was infected."

I was informed by a lady whose truthfulness I can vouch for, of a very interesting story. She told me that during the recent epidemic in New York a man came to the office where she is employed who was just recovering from the influenza. He said that his wife had died the day before of the disease. While speaking to him she noticed a bedbug on his collar. This bedbug was probably an influenza germ carrier, and if it crept to another individual may have transmitted the disease.

If it is possible for the bedbug to be a carrier of influenza and at times lead to an epidemic, the carrier must be able to retain the virus corresponding about to the duration of the acute stage of the epidemic. Chandler[21] states that the bacilli of the bubonic plague can develop in the gut of bugs, though more slowly than in fleas, and with a much higher mortality for the bugs. That they may act as transmitters of bubonic plague is quite certain, and bugs have been found to remain infective with this disease for forty-eight days. Bedbugs perhaps retain the influenza virus for about the same period of time and this would explain the duration of an acute outbreak of the epidemic in a certain place.

The theory of transmission of the influenza virus through the bedbug explains the difference between the epidemiology of influenza and that of typhus.

Typhus epidemics occur in the winter and in cold countries because lice are apt to be more abundant in the crowded dwellings of the poor during this season. The poor remain indoors and do not bathe often. The absence of proper ventilation and sufficient light create such unhygienic conditions that the vitality of the poorer classes is lowered. Bedbugs, as has been mentioned, are apt to be present in houses during the entire year.

Typhus is a disease almost exclusively of the indigent class, because the louse is rarely found in clean homes. Influenza, on the other hand, is frequent among all classes, because bedbugs are common and may be so widely distributed from place to place. Shipley[22] states that "bedbugs although unknown to the aboriginal North American Indians, had probably entered the continent with the best families on the *Mayflower*."

There are localities in some countries where influenza is endemic. This was definitely shown to exist in Russia by M. Teissier,[25] who was appointed in 1890 by the Minister of Public Instruction in France as the head of a commission to investigate influenza there. In the same locality in which I have observed sporadic typhus I have also observed sporadic influenza.

My observations have taught me that a patient afflicted with typhus will never contract influenza as long as he is in the febrile state, but frequently will become the victim of influenza as soon as he enters the convalescent state. The same holds good in influenza patients, for they do not contract typhus as long as they remain in the febrile state.

On several occasions I have seen influenza in the same patient complicated with malaria, as well as typhus with malaria, but I have never noticed typhus and influenza in the same individual simultaneously. It seems that individuals afflicted with typhus acquire a temporary immunity for influenza and vice versa. Based upon this observation, in a discussion on a recent paper of Dr. Thompson, I suggested trying the serum of typhus patients for the treatment of influenza and typhus vaccine for the prevention of influenza.

Bedbugs are not carriers of typhus, probably because they fear the body louse. According to a recent report of Hall[24] from Texas, body lice were placed in a bottle with head lice, bedbugs, and a piece of beef. The body lice first ate the head lice, then the bedbugs, and then the beef.

In the histories of epidemics of influenza, mention is often made that men are affected by the disease in larger numbers than women. These statements are probably correct, for men travel in larger proportion and thereby are more liable to bedbug infestations. I do not know if this statement is true for the present pandemic. Adhering to the theory of bedbugs, this may not be true since numerous men were prevented from traveling on account of war conditions. There is no difference between the two sexes in typhus, because typhus seems to be a louse-borne disease, lying dormant in isolated places.

Epidemics of influenza first manifest themselves in the city and later in adjoining towns and villages; outbreaks of typhus may occur in the villages first, and later in the cities.

The present epidemic kept the practitioner so extremely active that he could not devote any time to gather facts or perform experimental work. Now, when times have become more favorable for experimentation, little of the disease is observed. However, as history repeats itself also in medicine, we must bear in mind that the enemy may attack us again in the spring with the increased activity of bedbugs in nearly every climate; and with the increase of intercourse between the Eastern continent and this country the germ carriers will again be brought to our shores on ships from whence they will be disseminated to hotels, trains, and the homes of rich and poor alike, when another epidemic may be predicted. Preventive measures should be strict in destroying the pest for the best means of which entomologists should be consulted. This may prevent an epidemic which is so feared by the health officers and public.

Hagler,[26] who worked with the American Red Cross expedition in Serbia in 1915, points out that while typhus disappeared with the extermination of lice, relapsing fever continued to develop in the Belgrade hospital until the latter was fumigated for bedbugs. Every plausible advice should be followed as the world has experienced an epidemic which, using Biggs'[26] words was the "most serious that had visited the civilized world in a century." We should try to prevent "bugginess" just as the Germans prevented "lousiness" and saved their army from typhus which has so affected their neighbors, the Serbs, during the present war.

1000 PARK AVENUE.

THE STREPTOCOCCUS MUCOSUS CAPSULATUS INFECTION IN THE MASTOID.

BY J. MORRISETT SMITH, M.D.,
NEW YORK.

THE *Streptococcus mucosus capsulatus* has proven to be the most insidious as well as the most virulent infection with which we have to contend in cases of acute mastoiditis.

Smears examined from chronic ears always show a mixed infection, unless there happens to be an acute exacerbation of the chronic condition, and are not of much assistance to the otologist; while smears from cases of acute otitis media show either pneumococci or streptococci, and too much stress cannot be laid upon the importance of determining whether the organism is encapsulated or not. I might add here that a report of staphylococcus from a smear taken from an acute ear usually means a skin contamination and another examination should be had.

At the present time there is some doubt as to whether the so-called *Streptococcus mucosus capsulatus* is not really a pneumococcus mucosus of group three.

Doctors Avery, Chickering, Cole, and Doeberg, in a monograph on pneumonia from the Rockefeller Institute, October 16, 1917, make the following statement: "Considerable confusion still exists in bacteriological literature regarding the identity of the so-called pneumococcus and *Streptococcus mucosus*. Pneumococci of type three are bile soluble, ferment inulin, possess voluminous capsule, are extremely virulent for mice, and produce a greenish discoloration on blood media. *Streptococcus mucosus*, on the other hand, while having a similar mucoid confluent colony possessing a capsule, is not bile soluble, does not split inulin, is not so pathogenic for mice, and has a greater tendency to produce hemolysis on blood agar. Finally this organism, like other streptococci, does not react specifically with antipneumococcic serum."

Technically, it would seem that we at times really have an encapsulated streptococcus and at other times encapsulated pneumococcus, but for practical purposes we are enabled to make no distinction in the symptoms, and the term "*Streptococcus mucosus capsulatus*" seems to be suitable.

This infection when present is fairly easy to demonstrate under the microscope, care being taken to cleanse the external auditory canal with a sterilized cotton wrapped toothpick and then obtain the smear from the opening in the drum, fix it in the flame, stain with dilute carbolfuchsin (1 in 20) from three to five minutes. The capsule, if present, is usually well defined, can readily be detected under the oil immersion lens (1/12).

The importance of recognizing the presence of this organism is realized when we find that practically one hundred per cent. of the cases come to operation. I have seen only one case that did not become operative, and that one was watched very closely, had repeated *x*-ray examination, and was finally discharged as cured.

The onset of these cases resembles that of any other otitis media, but as soon as the pain is relieved by spontaneous rupture or an incision of the membrana tympani, the case is usually distinguished by an entire absence of symptoms; there may be a complete destruction of the mastoid structures and aside from the discharge, the patient will insist that he feels quite normal. This process will continue without pain, temperature, mastoid tenderness, or prostration, and if uninterrupted a meningitis intervenes and the death of the patient occurs.

Certainly this germ would play an important part were it possible to correlate the yearly deaths from mastoiditia, especially the unoperated cases.

These cases practically always occur in adults. I have seen only one in a person under twenty years, and am able to find in the records of the New York Eye and Ear Infirmary only one patient under nineteen years of age.

A large percentage of the patients have diabetes. Of my own cases, about three-fourths had a glycosuria and its presence seems to favor this infection. The reason for this I am unable to offer. Every case showing this infection should have a careful glycosuria test, since it may be the means of discovering a latent diabetes.

These cases are peculiarly apt to have an isolated focus of the infection remain in some part of the mastoid; the drum may entirely heal with later on a sudden recurrence of the discharge. This explains the fact that some of these patients die two or three months after the initial infection.

On physical examination the drum will often show a teat-like projection from which pus will exude when removed with a cotton-tipped applicator. This, of course, is not pathognomonic, but is suggestive of a capsulatus.

One case, in a man of twenty-eight years, after a thorough myringotomy, discharged for about ten days, the drum healed, and was restored to normal. Five days later he returned with a thick purulent discharge and an immediate operation showed a capsulatus with a perisinus abscess which a smear, had it been taken, would have shown me at first.

Another case, a man of thirty-two, had a six weeks' history and a large postauricular swelling, extending well down below the mastoid tip, also a facial paralysis. The smear revealed a capsulatus; operation showed a perforation in the lower part of the facial ridge. The facial paralysis was recovered from in about six weeks.

The most interesting case was that of a man thirty-eight years of age with a three months' history of trouble in the left ear and seven incisions of the drum.

Examination showed a normal drum with a slight red streak running down the handle of the malleus and a small postauricular swelling with no furunculosis, scalp or other lesions present. A capsulatus was suspected and upon obtaining a history of diabetes immediate operation

was advised, and in spite of a practically normal drum a perisinus abscess was found with an encapsulated streptococcus present; a severe nephritis occurred, but cleared up and the patient recovered.

The writer feels that these cases are amenable to surgical treatment. In the cases operated on personally, there have been no deaths, but at the same time I am cognizant of the fact that in spite of prompt recognition and a careful operation some of the cases will die of a meningitis, and we are in no way able to account for the route of intracranial invasion—the most likely being the blood or lymphatics.

At the time of the operation, the cells must be thoroughly exenterated, and care should be taken to avoid the exposure of sinus or dura, if possible.

The following conclusions were drawn from a series of about twenty cases operated on by the writer at the New York Eye and Ear Infirmary and the New York Polyclinic Hospital, as well as quite a number of other cases which have come under his observation at the above institutions.

Conclusions.—This infection rarely occurs under twenty years of age.

A high percentage of the patients have diabetes.

The symptoms are very apt to be masked, even in the presence of an extensive destruction in the mastoid process.

One of the chief dangers is that of not recognizing the presence of this infection.

Practically all of the cases come to operation.

Prompt recognition with early and careful surgical intervention will result in a uniformly low mortality.

45 East Sixty-second Street

SAWDUST SURGICAL HANDRUB.

By F. GRIFFITH, M.D.,

NEW YORK.

FELLOW, ACADEMY OF MEDICINE.

For a time the writer was engaged in a navy airship shop and noticing some of the work people scrubbing their hands habitually with sawdust in running water in place of using soap for cleansing purpose, he became interested in considering the possible and practical value of the method for use by surgeons. The raw scrub with soda crystals, chloride of lime, permanganate of potash, and oxalic acid as used in many hospitals for routine service at the wash stand spoils the velvet of the skin on the hands of many operators and probably makes such hands so much the more dangerous as septic carriers and pus contaminators to the surgical wound than when blander methods obtain combined with the strictest technique to avoid touching the "unclean" things in the surgical world.

We used clear grained mahogany, spruce, and pine for the flying seaboats and the wood dust from the bandsaw was found best for cleaning use for hands at the taps; a handful of the hardwood sawdust rubbed over the surfaces in the running water left the extremities clean as though soap had been used, besides leaving the skin in a pliant condition after its employment. It should be conceded by those who insist upon the employment of the strong and stressful lime, soda, and oxalic crystals that the mixing up of half as much sawdust as chemical in the containers would lessen the skin damage and leave the operator's hands equally safe.

It might be objected that sawdust if generally employed about hospitals would clog washbasin wastepipes, but this danger need hardly be noticed for the reason that fine sawdust tends to separate the particles so that they do not lump in running water, and the lightness of the sediment further adapts it to be conveyed unresricted. The use of sawdust from yellow pine, or fat pine as it is called, sometimes containing much oleoresinous substance of natural antiseptic nature when the turpentine has not been previously extracted from the tree, would prove its worth as a drier of the skin surfaces, especially to replace the chalk and talcum dusting powders where rubber gloves are to be donned. All sawdust for surgeons' use can be readily and positively sterilized by baking, and that it has value as a decided general cleanser has long been noted by the jewelers. Its adaptation for cleansing away excess oil and scurf and extraneous matter and attached germs from the skin of hands and arms of the surgical operator, aside from being a mere mechanical rub, is not an impractical suggestion.

Medicolegal Notes.

Instructions as to Care and Skill Required.—In an action for malpractice against a hospital company and one of its physicians it appeared that in July, 1913, the hospital company agreed to provide for the plaintiff all necessary medical and surgical treatment, and all necessary medicines and hospital services during the period involved in the action; that in November, 1914, the plaintiff contracted a cold and needed medical treatment therefor; that the company assigned one of its physicians to the case; that the latter failed to use ordinary diligence, care and skill in treating the plaintiff, and that by reason of such failure the plaintiff's sickness progressed unfavorably, he became unable to work, was confined to his room, and continued to grow worse until he became afflicted with pulmonary tuberculosis, and that he was put to great expense in procuring subsequent treatment therefor. The plaintiff was awarded a verdict and judgment against the hospital and its physician for $2,500. The defendants appealed.

The principal contention of the appellants was that errors were committed in the court below in giving, refusing, and modifying instructions to the jury. Instruction 5 was to the effect that a physician is liable to damages if he fails to give "proper" advice to his patient. Instruction 10 reiterated this doctrine. Instruction 6 gave the jury to understand that a physician is guilty of malpractice, and liable to damages, if, in treating a patient, he fails to do anything necessary to obtain an approximately perfect result. The California Supreme Court said that the law does not require that the instructions and advice given by a physician to a patient should be at all events and beyond question "proper," or that his treatment should be certainly such as to obtain an approximately perfect result. It requires only, first, that he shall have the degree of learning and skill ordinarily possessed by physicians of good standing practising in that locality; and, second, that he shall exercise reasonable and ordinary care and diligence in treating the patient and in applying such learning and skill to the case. The law takes cognizance of human weakness and liability to err in the application of skill and learning, and it requires only the exercise of reasonable and ordinary care and diligence to avoid error. The instructions given required more; they required that the advice given should be "proper," which implied that no error should be committed; they required that the physician should do everything necessary to be done to produce an approxi-

mate perfect result; that he guarantees that his treatment shall be of the best quality; whereas, the law only demands that he use reasonable care to attain such approximate perfection. Instruction 9 declared that the physician is bound to use, and of course to have, a degree of skill "adequate" to the performance of his undertaking; the law requires that he have the degree of skill ordinarily possessed by reputable physicians in that locality. This may or may not be "adequate" to the performance of his undertaking, according to the meaning to be given to the word "undertaking." If it was intended to mean that he undertakes a cure, or to produce a result approximating perfection, as stated in instruction 6, or that he undertakes to use the highest possible degree of skill, the standard was held to be higher than the law requires. The instruction was uncertain on that point, and it may have misled the jury.

The court below in other instructions stated the rule by which the defendants were bound accurately and clearly. There was a clear conflict in the instructions. The Supreme Court was unable to determine which set of rules the jury followed. The plaintiff's case, on the merits, was not strong. It could not be said that these instructions were not injurious to the defendants, and did not improperly control the deliberations of the jury in rendering a verdict. For these reasons the judgment for the plaintiff was reversed.—Hesler v. California Hosler Co., California Supreme Court, 174 Pac. 654.

Inflammation of the Brain Caused by Puncture Held Accident.—A policy of insurance covered "loss or disability resulting directly, independently, and exclusively of all other causes from bodily injuries effected solely through accidental means." In an action on the policy the question was whether injuries resulting in death were affected by accidental means within the meaning of the policy. The trial judge dismissed the complaint. The New York Appellate Division, two justices dissenting, affirmed. The case was carried to the Court of Appeals. On July 6, 1915, the insured had a pimple on his lip. A friend who lunched with him testified that it looked like an ordinary pimple at that time. A day or so later it was larger and more inflamed. On July 10 the insured consulted a physician. The physician's testimony was that there was then a punctured wound in the lip, which had inflamed and infected the deep tissues. The lip was opened by the physicians, and remedies were applied. They were of no avail. The infection spread through the cheek toward the eye. A week later, July 17, the insured became paralyzed and blind. He died the next day. His death was due to inflammation of the brain produced by the germ known as the *Staphylococcus aureus*. There was little doubt that the germ came from the infected pimple. If the infection was the result of accident, the defendant was liable. The Court of Appeals thought there was testimony from which a jury might find that the pimple had been punctured by some instrument, and that the result of the puncture was an infection of the tissues. If that was what happened, there was an accident. The court has held that infection resulting from the use of a hypodermic needle is caused by "accidental means." Bailey v. Interstate Casualty Co., 8 App. Div. 127, 40 N. Y. Supp. 513; Id, 158 N. Y. 723, 53 N. E. 1123; Marchi v. Ætna Life Ins. Co., 140 App. Div. 901, 125 N. Y. Supp. 1130; Id., 205 N. Y. 606, 98 N. E. 1108. The same thing must be true of infection caused by the puncture of a pimple. Unexpected consequences have resulted from an act which seemed trivial and innocent in the doing. Of itself the scratch or the puncture was harmless. Unexpectedly it drove destructive germs beneath the skin, and thereby became lethal. To the scientist who traces the origin of disease there may seem to be no accident in all this. "Probably it is true to say that in the strictest sense, and dealing with the region of physical nature, there is no such thing as an accident." Halsbury, L. C., in Brintons v. Turvey, L. R. 1905 A. C. 230, 233. But the Court of Appeals said that its point of view in fixing the meaning of this contract must not be that of the scientist. It must be that of the average man. Brintons v. Turvey, supra; Ismay v. Williamson, L. R. 1908 A. C. 437, 440. Such a man would say that the dire result, so tragically out of proportion to its trivial cause, was something unforeseen, unexpected, extraordinary, an unlooked-for mishap, and so an accident. This test—the one that is applied in the common speech of men—is also the test to be applied by courts. United States Mutual Acc. Assn. v. Barry, 131 U. S. 100, 9 Sup. Ct. 755, 33 L. Ed. 60, etc. The defendant argued that the puncture may not have caused the infection. But the plaintiff's experts said that in their opinion the entrance of the germs from the skin into the deeper tissues was the result of trauma. They said that trauma is almost invariably the cause of such infections. The court found the signs of trauma here in the punctured wound which was visible when the physician was first consulted. The insured was an athlete in the prime of life and the fullness of health; the infection was not due, therefore, to lowered powers of resistance. The punctured wound was an adequate cause. The evidence suggested no other; at least, a jury might so find. The judgment was reversed, and a new trial granted.—Lewis v. Ocean Accident & Guarantee Corp., 120 N. E. 56.

Accident or Disease—Heat Stroke and Sunstroke.—The Rhode Island Supreme Court holds that a fireman employed in a boiler room, who in the afternoon was overcome by excessive heat and afterwards was taken to a hospital, where he died the following morning from heat exhaustion, died as the result of "personal injury sustained by accident" within the Workmen's Compensation Act, and not from disease of heat exhaustion or from occupational disease; the word "accident" as used in the various workmen's compensation acts not being one of precise meaning. The court said: "It appears to us that the unusual and excessive heat in the boiler room, producing the sudden inability of the physical system of John Walsh to longer resist its debilitating effects, constituted a chain of circumstances which may fairly be regarded as an unlooked-for mishap not designed and undoubtedly unexpected. If by reason of the condition of the floor of the boiler room the deceased had slipped and had fallen, as a result of which a disease had developed in his brain causing his death, we think no one would have questioned that the injury was produced by accident. Can it reasonably he regarded as otherwise when by reason of the high temperature of the air in said room his physical and mental stability is overthrown, and a physiological derangement is set up which causes his death? The respondent has claimed that the effect of the heat upon said Walsh was not sudden, for he complained of it in the afternoon. That he should have been made uncomfortable by the heat was to be expected; but the collapse of his physical resistance may fairly be said to have been suddent.

We think that in thus viewing the occurrence we have not confounded the injury with the accident. The untoward event which in this case produced the disability from which John Walsh died was the aggregate of the circumstances culminating in the breaking down of his physical stamina." The court added that the word "accident," as usually interpreted in workmen's compensation statutes, will, in most cases, be applied to both heat stroke and sunstroke.—Walsh v. River Spinning Co., Rhode Island Supreme Court, 103 Atl. 1025.

Validity of Harrison Act.—The Federal District Court for the Southern District of New York holds that section 2 of the Harrison Anti-Narcotic Law, forbidding any person selling opium to another not presenting a written blank furnished by a revenue collector is not invalid as a revenue resolution, though its chief purpose may be to control distribution, by empowering physicians exclusively to distribute the drug only as a medicine, and thereby suppress consumption by addicts. The court pointed out that the authorities are somewhat doubtful upon this point. The Circuit Court of Appeals for the Sixth Circuit, in Webb v. U. S., certified the question to the United States Supreme Court on February 11, 1918. In U. S. v. Doremus, 246 Fed. 958, the statute was held unconstitutional in the District Court, and the Supreme Court had enough doubt of section 8 in U. S. v. Fuey Moy, 241 U. S. 394, 36 Sup. Ct. 658, to feel obliged to impose upon it what the court itself recognized as a forced construction. On the other hand, section 2 was enforced in U. S. v. Curtis (D. C.) 229 Fed. 288, though without consideration of its constitutionality.—United States v. Rosenberg, 251 Fed. 963.

Military Medicine.

Flavine and Dakin's Solution.—Although a war of immense range and one in which injuries have been incurred on a scale and of a character unheard of before has gone on for more than four years, the question of preventing sepsis in wounds is still one regarding which much disagreement exists among leading surgeons. And yet it would appear that certain antiseptic methods have made a great deal of progress in this direction and that in those instances in which such methods have been applied scientifically and thoroughly, in the manner in fact which their originators directed, the results have been remarkably good. According to Carrel, by employing the Carrel-Dakin methods properly, suppurating wounds and old fractures can be rendered sterile, while complications resulting in the death of the patient or the amputation of the limb may be almost entirely avoided. Again, conspicuous success has been obtained by the treatment of infected wounds by flavine bodies, acording to the testimony of many surgeons. In the hands of Rutherford Morison and in those of a very large number of surgeons "bipp" has acted in an extraordinarily effective way in subduing infection of wounds.

If then, antiseptic treatment of septic wounds has met with so great success and has received unqualified endorsement to this effect from the mouths and the pens of so considerable a proportion of the medical profession, why is it that the best recognized methods of procuring asepsis are still regarded with a certain amount of scepticism and their merits minimized by others of the same profession who carry equal weight and authority?

Mr. John Macintyre, in the *Glasgow Medical Journal* for November, 1918, endeavors to answer this question. He is of the opinion that specialization in the best known methods is required in order to afford fair opportunities for effective demonstration of their worth. That is to say, that there should be flavine hospitals where the flavine bodies are specialized in, and their action more fully investigated; Carrel hospitals where the Carrel-Dakin method is properly carried out and exclusively used and studied, and so on. The methods referred to have sufficiently proven their value to warrant their being employed thus without giving rise to the cry of "hospitals for experimental purposes."

Macintyre tabulates the several reasons why the wonderful properties of new antiseptics have not been duly appreciated by those in administrative power, and by many surgeons whom they control, as follows: (1) Insufficient investigation of the results, even when the methods are properly carried out. (2) Reports, to use Carrel's own words, of "deplorable results obtained in several hospitals by surgeons who believed they were using our methods, but who, in reality, were altering them according to their fancy." (3) Insufficient appreciation of the fact that the new antiseptics are antiseptics for a special purpose, viz., for infected wounds. They are not meant to sterilize instruments or ligatures, or any other thing; they are specialized for definite purposes. (4) A certain amount of overcaution, or *vis inertiæ*, common to all officialdom, a useful element in all organized work, but deadly to scientific progress. Probably this is the weightiest factor.

Moreover, and this is a very important point, Carrel-Dakin's and Browning's antiseptics, solution of sodium hypochlorite and flavine, act not by their unaided power alone in the wound, but in combination with substances produced by the living tissues. Browning has shown that conjunction with the serum of the wound enhances the antiseptic properties of flavine, and Carrel has demonstrated that the solution of sodium hypochlorite combines with the proteins of the wound, when a chloramine is formed, destructive to pathogenic organisms, but not to body cells.

Macintyre is an enthusiast for the Carrel-Dakin method and for flavine, and goes so far as to say that not only do infected wounds heal more rapidly by far by the Carrel method, but that the technique of this method does not take up more of the nurse's time than the older methods. Macintyre has been thoroughly convinced by fifteen months' work among the infected wounded that by the antiseptic methods introduced by Carrel and Browning a long leap forward has been made in the manner of treating infected wounds, and he deprecates the lack of generous recognition of these wonderful life saving means.

Recently, many if not the majority of surgeons have claimed that thorough and continuous drainage of infected wounds was of more consequence by far than the application of any particular antiseptic, and that with regard to the antiseptic the technique of its employment was really what chiefly counted. Consequently, the contention was that the good results obtained by the use of the Carrel-Dakin method were due to the way in which it was carried out. *Per contra*, it might be asserted that the unsatisfactory results of the use of the method were owing to the inadequate way in which it was employed. However, Macintyre and many others, while allowing that the method must be employed properly to exert its full antiseptic action or germ abolishing rôle, at the same time hold that in themselves this antiseptic and flavine are remarkably potent factors in rendering septic wounds sterile.

The War's Toll in Dead and Wounded.—The various nations who were participants in the war have been counting the cost in human life. Statistical reports coming in show that the British losses on all fronts during the war were 4,003,993. The British wounded totaled 2,938,122, the dead 706,726, while the missing, including prisoners numbered 359,145. According to a statement made in the French Chamber of Deputies, 1,400,000 French soldiers were killed during the period of the war. Salvatori Brazilai, a former member of the Italian Cabinet, speaking recently in Paris, stated that the Italian losses included 200,000 soldiers who lost their lives in battle and 300,000 who died of disease, particularly malaria, contracted in Albania, Macedonia, and along the Piave; the severely wounded numbered 300,000. The *Cologne Gazette* of October 25 publishes the total German casualties to that date as 6,066,760, of which 4,750,000 were Prussians. The number of dead among these is placed at 1,611,104, the number of wounded at 3,683,143, and the missing

at 772,522. The paper says that of the number missing 180,000 may be considered dead. The casualties of the Austro-Hungarian armies from the beginning of the war to the end of May, 1918, were slightly over 4,000,000 men according to official statistics from Vienna. Estimates of the Russian casualties announced by the Russian Information Bureau Director figure the total at not less than 9,150,000 men, of whom 3,000,000 were killed and about 1,000,000 disabled for life. Serbia lost 320,000 men in killed, wounded and prisoners. The American casualties in the war number 236,117. Of these 36,154 were killed or died of wounds, 14,811 died of disease, and 2,204 are unclassified. This would make the appalling total of more than eight and one-half millions dead and a far larger number of wounded. An inspection of these figures shows that they are by no means complete in many respects and that when the final reckoning is made the figures will be still greater.

Wounded and Sick Soldiers Return.—During the week of December 20 a total of 7,468 wounded and sick soldiers were landed in the United States from the American Expeditionary forces. This was the largest number received in any week. Of this total 5,828 were landed in New York, and the balance of 1,640 at Newport News. The men are distributed from these ports to the various army hospitals and convalescent camps. There were, on December 24, 42,077 sick or wounded soldiers, sailors, marines, and nurses in New York or nearby hospitals, and for every ward in these hospitals the Red Cross provided a Christmas tree. Canes were distributed to every enlisted man inscribed "Red Cross 1919." The Red Cross presented more than 3000 sailors and marines with fountain pens.

Another Philanthropic German Scheme.—The chief engineer of the steamship *Fredrica*, which is here from Iceland reports a conversation with a German scientist who revealed to him Germany's plans to make drug fiends of all the nations which opposed her. German scientists and chemists had planned to accomplish this by introducing morphine, cocaine, and other habit-forming drugs into patent medicines, tooth pastes and powders, and into well known and much used prophylactic preparations. They had progressed so far as to distribute tooth paste containing drugs among the natives on the coast of Africa, who, without knowing why, enjoyed the sensation which resulted from its use and became addicted to it.

Passaic Doctor Decorated.—Lieut. Robert MacGuffie, who served with the Royal Warwickshire Regiment of the British Army and was wounded by a high explosive shell, November 1, at Valenciennes after being under fire for five months, has received the British War Cross for gallantry and devotion to duty under shell fire and machine gun fire in the front lines. He was gassed and then wounded. He has been operated on three times in France and a fourth time in the London General Hospital. The English surgeons who are attending him are confident that he will in time make a complete recovery.

Asks Release of Army Doctors.—Springfield, Mass., with about 70 local physicians now in the United States service in this country and abroad, and suffering by reason of a renewed influenza outbreak, has through its Department of Health sent a request to the War Department that a part of these doctors be released to meet home needs.

Wounded Men in New York Hospitals.—According to a recent Red Cross report, there are 42,077 sick and wounded soldiers, marines, and nurses in the hospitals of New York and the vicnity, including the Debarkation Hospitals, in the old Greenhut Building, Ellis Island, Hoffman Island, Grand Central Palace, Polyclinic, Fox Hills, and Base Hospital No. 1 on Gun Hill Road.

American Expeditionary Forces Escaped Epidemic.—According to a report prepared by the Chief Surgeon in France and published in the Stars and Stripes, in the nine weeks from September 6 to November 8, at the time when the American Army 2,000,000 men was doing its heaviest fighting, the total deaths reported from all causes, diseases as well as losses in battle, were 19,750. This report points out that in the army in the United States although the men in camps and cantonments was approximately half the number in France, the total deaths were 19,580. It is estimated that the proportionate rate for influenza and pneumonia in the A. E. F. in France for the same period was only one-eleventh that of the United States.

Influenza in the Army and Navy.—An official statement issued by the Surgeon General's office, on December 28, states that influenza is again definitely on the decline in the army camps. Not a single new case was reported in several of the larger camps for the week ended December 20. At Camp Devens, Ayer, Mass., strict precautions were taken against the possible bringing into the camp cases of influenza. Medical officers examined every man on his return. The experiments which have been carried on at the naval hospital at Gallups Island to determine the cause of influenza and the manner in which it was spread have been abandoned, as it was found impossible to produce the disease experimentally. Pfeiffer's bacilli were placed in the nostrils and throats of volunteer subjects and were fed them in their food, and groups who had been given the germs were huddled in close quarters, but the only result was that the men gained in general health. The Coast Guard Stations at Narragansett Pier and Fisher's Island are experiencing an outbreak of influenza.

Inadequate Hospital Accommodations Charged.—Senator Chamberlain of Oregon, chairman of the Military Affairs Committee, in the course of a long speech on December 30, charged the War Department with many delinquencies, among others with having provided insufficient hospital accommodation for the returned sick and wounded soldiers. "Pursuing the dilatory policies we pursued during the war with reference to getting ready to fight," he said, "we are pursuing the same dilatory policies with reference to getting ready to take care of these young men. We are getting word from every hospital and cantonment that the conditions for taking care of these young men are bad. There are 179,000 of them, in round numbers. Where are the hospitals that they are going to put them in? What I am criticising is

not having hospitals ready. We knew when we assembled these men in cantonments that they were going to be sick, but there were no hospitals prepared. Therefore, there were thousands of deaths that ought to have been avoided. We have not now hospitals prepared to accommodate all these wounded men who are coming back, and, therefore, we are going to have a great deal of suffering." Secretary of War Baker, in replying to the charges brought against his administration, admitted that certain of them had some foundation in fact, but denied emphatically that there was any lack of hospital facilities for caring for the sick and wounded soldiers. Complaint has also been made that the American troops in Archangel, Russia, are inadequately supplied with clothing and that an insufficient medical force accompanies them. The outfitting of this force is under the direction of the American army authorities in London.

Brutality in German Hospitals.—A British officer with a paralysis of the hand tells the story of a Hun surgeon who while dressing his arm, touched it in a certain region remarking, "That is the nerve," the British officer understood and speaking German replied, "Yes, that is the nerve." The German surgeon then said to his assistant, "Here is an Englishman who understands German. Now you shall see how an Englishman can scream." He then had the prisoner's arm placed over the assistant's shoulder and bound to his back, and gave the nerve six jabs with an instrument. This beastly performance occurred in a hospital near Metz about the first week in June, 1918. At Wevelgham, last May, a sergeant in charge of a ward hit a delirious patient in the mouth, knocking his teeth in, because the unfortunate patient had placed his hand under his bandage during his delirium, displacing it. The German sergeant had been a priest in civil life.—*New York Medical Journal.*

One hundred and ninety American prisoners arrived early in December at Nymegen, Holland, where they were interviewed by a correspondent of the *New York Times.* These men were from the 106th and 107th Regiments and were mostly from Manhattan, Brooklyn and North Carolina. They had been held in the Bulmen camp. All stated that their treatment was barbarous at the detention camp, many who were only slightly wounded dying owing to gross neglect. The German doctors refused to give adequate attention to slight wounds which they said could wait. This was inexcusable, as plenty of doctors were standing around doing nothing. They appeared to be only interested in frightfully mutilated cases. The wounded were often obliged to walk many miles with undressed wounds. One man had a slight bullet wound in the arm. Attention was refused and he was made to walk miles, his wound getting worse till blood poisoning set in and he died.

Maj. H. Nelson Jackson, M. C., U. S. Army, of Baltimore, arrived in this country from France on December 29. He served as a staff surgeon with the 313th Infantry and was wounded three times. The third wound received at Montfaucen, on September 29, permanently disabled him. The shrapnel from a high explosive which wounded him killed a soldier whose wounds he was dressing at the time.

Deaths in the Service.—Major Howard Walter Beal, M. C., U. S. Army, of Worcester, Mass., a graduate of Harvard Medical School, in 1898, died of wounds received while on duty with the American Expeditionary Forces in France, on July 18, 1918, aged 49 years. He was a member of the American Association of Genito-Urinary Surgeons and the American Urological Association, formerly assistant acting surgeon in the United States Army, surgeon to the out-patient department and cystoscopist to the Worcester Memorial Hospital, and cystoscopist to the Worcester City Hospital.

Capt. Stephen John Henry Reed, M. C., U. S. Army, of Fultonville, N. Y., a graduate of the Albany Medical College, in 1907, on duty in France with the One Hundred and Thirtieth U. S. Infantry and the One Hundred and Thirtieth Field Hospital Sanitary Train No. 108, was killed in action on October 21, aged 37 years.

Lieut. William Thomas Murphy, M. C., U. S. Army, of Waukesha, Wis., a graduate of the Wisconsin College of Physicians and Surgeons, in 1904, on duty with the Three Hundred and Thirtieth Aero Squadron, died from pneumonia following influenza, in a hospital in Grantham, England, on November 2, aged 38 years.

Maj. Clude Edward Prudden, M. C., U. S. Army, of Duluth, Minn., a graduate of the North Western University Medical School, Chicago, in 1909, is reported in the Official Bulletin of December 2 to have died of disease in France at the age of 30 years.

Lieut. William Sarsfield Morriss, M. C., U. S. Army, a graduate of the Harvard Medical School, in 1915, on duty at Camp Joseph B. Johnson, Jacksonville, Fla., died of pneumonia, following influenza, while on a furlough at his home in Fall River, Mass., aged 29 years.

Lieut. Clarence Howarth White, M. C., U. S. Army, of Cohoes, N. Y., a graduate of the Homeopathic Medical School, Ann Arbor, 1909, aged 30 years, is reported to have died of pneumonia in a military hospital in France on November 12.

Capt. James Malcolm McKibbon, M. C., U. S. Army, of Buck Valley, Pa., a graduate of the University of Pennsylvania, in 1899, aged 46 years, died in Mobile Hospital No. 4, in France, on October 23, from wounds received while on duty on the fighting line.

Capt. Benjamin William Carlson, M. C., U. S. Army, of Denver, a graduate of the University Medical College of Kansas City, died from pneumonia at Kelly Field, South San Antonio, Texas, on November 20, aged 44 years.

Lieut. William Frank Guilfoyle, M. C., U. S. Army, of Philadelphia, Pa., a graduate of the University of Pennsylvania, in 1905, aged 36 years, died after having been gassed while on duty with Base Hospital No. 31 in France, on September 2.

Lieut. Albert Marinius Larkin, M. C., U. S. Army, of Jasper, Minn., a graduate of the University of Minnesota, in 1917, died of disease in France, on December 2, aged 29 years.

GANGI'S REACTION.

AMONG the various reactions for the differentiation of exudates and transudates, the reaction of Gangi is certainly of value. It consists in pouring from three to four cubic centimeters of hydrochloric acid into a test tube, and adding four or five cubic centimeters of the liquid to be tested. If the liquid is an exudate, a white caseous disc immediately forms at the plane of contact of the acid with the liquid, and this gradually extends within the space of twenty-four hours, invading the serous fluid, forming a uniform, thick, shiny white or greenish mass. In the case of a transudate only a thin disc forms. This reaction permits one to control the indications furnished by the microscope by completing them in the case of mixed or illegible cytological formulæ, and what is yet more important is that in many instances the results of the cytological examination may be corrected by the indications offered by Gangi's reaction. Compared with other chemical reactions for the differentiation between exudates and transudates, it would appear to be more delicate than some and quite as delicate as the others, and as the technique of the reaction is of the greatest simplicity it is within the grasp of any practitioner.

In forty-two cases of ascitic fluid collected by Zettel (thesis, Paris, 1915) the results obtained by Gangi's reaction, as well as with other chemical tests, generally coincided with the cytological examination, so that a transudative nature could be attributed to early non-infected cirrhoses, while the characters properly belonging to exudates corresponded to old ascitides or those which had been frequently punctured. Occasionally, Gangi's reaction, as well as other chemical reactions, are even more demonstrative than cytology. They prove that certain cases of cirrhotic ascites which formerly would have been considered infectious in origin, on account of their mixed cytological formulæ (lymphocytes and polynuclears) are in reality mechanical collections. The study of the chemical reactions has shown that the symptomatic ascitides of Laennec's cirrhosis do not necessarily undergo an inflammatory evolution, as has been shown by Gilbert and Villaret in a case presenting the typical syndrome of portal hypertension in which a series of ten punctures was made and in which the cytological and chemical reactions invariably showed a transudate up to the time of the patient's death. Likewise, the study of cases of long-standing ascites in which puncture has not been made often reveals a mechanical process upon which no autogenous infection has become superadded, and these data have permitted Gilbert and Villaret to offer a new argument to the theory of a primary mechanical origin of peritoneal collections in alcoholic cirrhosis. Contrary to what is seen in ascitic or pleuritic collections, no matter what the pathological changes, the nature of the causal affection, and the cytological formula may be Gangi's, Rivalta's, and the collargol reactions have not resulted in precipitating the cerebrospinal fluid. Villaret attributes this fact to the special nature of the subarachnoid serosa, from the anatomical, histological, and physiological points.

To sum up, it may be said that modern investigations show that there exist three principal categories of serous collections: Firstly, pure mechanical collections. These are precipitated by the collargol test and not by those of Gangi and Rivalta, while cytological examination shows exclusively, or distinctly predominating, endothelial plates. They are generally encountered in alcoholic cirrhosis, either at the beginning or during the entire evolution of the process. Secondly, purely inflammatory collections, characterized by precipitation in Gangi's or Rivalta's test, and an antiprecipitating action of collargol and a cytological formula of pure lymphocytosis. These are met with in tuberculous pleurisy and ascites. Thirdly, the mixed collections. In these, either a spontaneous or a secondary infection, usually of tuberculous nature or following a series of punctures, supervenes upon a primary passive congestive process, and the cytological formula slowly changes. In serial examinations the fluid withdrawn successively shows that the polynuclears or lymphocytes progressively replace the epithelial plates. These changes are usually preceded by a negative Gangi reaction which later becomes positive. The precipitating action of collargol persists much longer, but finally disappears in its turn.

THE PATHOGENESIS OF TORSION OF THE OMENTUM.

AT present, the mechanism of torsion of the omentum has been solved to a certain extent only. The reported cases are as yet too few, and, it must be admitted, have been generally studied insufficiently, so that the pathogenesis cannot be definitely settled. Nevertheless, three general data should be mentioned, because they recur in all the published cases. They are, firstly, the constant coexistence of hernia with torsion of the omentum; secondly, the absence of the intestine in the hernial sac; and thirdly, the absence of strangulation by the hernial sac. In some instances the reporters have particularly insisted on the latter, and have pointed out that the finger could be passed up through the hernial sac into the peritoneal cavity.

The provocative cause has been placed in evidence in a certain number of cases. The accidents have appeared following upon an effort, or violent exercise on a bicycle, or yet after the reduction of an inguinal hernia. But in other instances the accidents have occurred suddenly under varying conditions, so that the causative factor escaped notice.

It is probable that in these various cases the pathogenesis of omental torsion is not always the same, and must be due to a different mechanism, according to the type of torsion. The mechanism seems simple enough when the torsion occurs between two adhesions. Under the influence of an irritative process frequently met with in cases of long-standing hernia, it is probable that adhesions became formed between the omental mass and hernial sac. This mass being thus fixed is much more markedly influenced by small traumata which may be inflicted upon a hernia, whether they result from a shock or an attempt at taxis or from the repeated pressure of a bandage, or perchance merely from intestinal peristalis.

The compressed omental mass may, and often is, thinned at the level of the ring, becomes displaced, and at length rolls up upon itself. Such is the mechanism of strangulation between two torsions that one can realize experimentally by twisting a napkin at both ends.

Torsion does not occur completely at once. It is probable that it takes place slowly, and in a progressive manner. Then, under the influence of a more intense trauma, or a slightly violent effort, the turns of the spiral become tightened and the phenomena of strangulation make their appearance. It is in this way, we believe, that the action of violent effort, essays at taxis, etc., which have in some cases immediately preceded and in appearance have been the means of producing the accidents, can be interpreted.

One may invoke the same mechanism for explaining the torsions *en masse*, but in these circumstances we are more inclined to attribute a preponderating influence to malformations of the edges of the omentum, to those thick, hypertrophied fringes that are often encountered, to cords overcharged with fat which can traverse them in any direction, forming true bands. Such conditions evidently prevent the easy unfolding of the omentum over the intestinal mass and favor displacement, or at least contribute to maintain it in a vicious position, should it take place. The changes of structure resulting from a former epiploitis, the thickening and fibrous degeneration, with retraction of the omentum, must likewise have some considerable importance from the pathogenic viewpoint. The hypertrophy of the fringes and the pedicellation which results have played the principal part in quite a number of cases.

INEQUALITY OF THE PUPILS.

It is common for beginning neurologists to be ever on the lookout for fine shades of diagnostic difference, and the pupils furnish a fertile field for hyper-examination. The various reflexes of the pupils are easily enough elicited, but the questions of size, shape, etc., are rather difficult to evaluate. Thus you will find the same patient examined by several competent observers who come to diverse opinions about comparative size, for example. As a matter of fact, there is hardly any more misleading symptom than inequality of the pupils. We see even experienced neurologists and psychiatrists pounce upon a real or supposed case of this kind and make it the basis of varied suppositions about organic brain disease. Too little, however, has been done toward making a systematic study of the pupils, or we should not have such dogmatic statements as those of Fuchs, who says that "inequality of the pupils is always pathological," and that of Foster, who says "a marked difference in size commonly is a pathological symptom."

Lately a Scotch physician has made a study* of a number of recruits sent up for special examination, and formed some interesting conclusions. Thus he found inequality of the pupils in over 10 per cent. of his cases, and in none of these was there evidence either of ocular disease or disease of the central nervous system. Barrie came to the following conclusions: (1) Inequality of the pupils is frequent. (2) It is associated with all the refractive conditions, with a tendency to be more frequent in myopic conditions. (3) The visual acuity is not affected adversely by the fact that one pupil is slightly larger than the other. (4) The left pupil is more frequently larger than the right. (5) Inequality of the pupils occurs as a physiological condition.

Therefore, it would seem that we must regard irregular pupils as a sign of little or no importance by itself, but only significant when occurring and taken into account with other neurological symptoms. At any rate, it has not such diagnostic value as the fixed pupil, or even the irregular one.

SACCHAROMYCOSIS.

Doctor Ramon Ribeyro in the *Anales dc la Facultad de Medicina* for September-October, after deploring the lack of interest in Peru in mycotic affections—which seems strange in view of their prevalence in South America and of the amount of attention which they are receiving in tropical medicine—proceeds to relate a case of a rare form of mycosis due to the yeast fungus. Every rebellious ulcerative process should be regarded as possibly a mycosis until this possibility is disproved. The patient was a young woman of 22, eight years resident of Lima, never ill, and free from syphilitic taint, the Wassermann being negative. On December 4 she fell and hurt her lower lip. Iodine tincture was at once applied over the region and provoked a cheilitis for which a soothing ointment was applied. The condition became a permanent one, rebellious to all treatment. From the description the lips were the seat of a condition much like an obstinate eczema, swollen, red, edematous, and weeping,

*Inequality of the Pupils. By T. Stewart Barrie, M.B. *British Medical Journal*, Nov. 8, 1918.

covered with yellowish brown crusts. The discharge contained pus. In places the lips were raw and here the crusts were readily loosened. The process had spread around the lower lip and had slightly involved the upper. The fluid contained many yeast cells, from which cultures were made. The strains which developed were evidently distinct from the familiar ones known to mycologists. Animal experiment gave negative or inconclusive results. Thus far no pathogenicity had been shown. The author believed infection had occurred through the ointment, which was said to have been rancid and irritating. No proofs were obtained, however, so that the treatment test alone remained. A 5 per cent. solution of sodium bicarbonate was applied and also the same drug was given inwardly. The condition soon showed marked improvement and the discharge was seen to contain fewer yeast cells. In eight days recovery was complete, after six months' persistence.

Pathomimic Elaiopathia.

By this term Tommasi, in the *Giornale di Medicina Militare* for October 31, refers to the consequences of injecting liquid vaseline subcutaneously. The author does not appear to regard in this connection the embolisms of the lungs which may follow injections but merely the local results in situ when disease is to be simulated by soldiers and others. The word pathomimic is used chiefly for conscious simulation practised for a definite motive. The substances presumably injected as well as the lesions provoked having shown much variation, the author made experiments with a view of determining the article chiefly in use. The testimony from the men themselves was unsatisfactory for several reasons. Despite the length of the author's paper his conclusions are quite brief. He found by outside and experimental evidence that so-called vaseline oil was in all likelihood the substance employed in the great majority of cases. It provokes a transitory and brief phase of acute eleopathic phlogosis, which is followed in turn by a long subacute phase which may be termed eleopathic edema, this corresponding to collateral inflammation in ordinary pathology. It is this phase which is so difficult of detection in simulation. Moreover, this phase may be complicated by other artifacts, the results of constriction of a limb, direct trauma, etc. The terminal phenomena comprise cysts, nodules, and scabs.

The Pneumococcus and Italian Bacteriologists.

The *Riforma Medica* publishes photographic reviews of various scientific subjects in which likenesses of all those who have aided in the development of the same appear in miniature. In a review by Ferrannini of pneumococcal infections, it appears that, while native sons were not the first to describe the pneumococcus and its activities, they have done much to further the development of our knowledge. Bozzolo showed that this germ is able to produce in addition to pneumonia many other local inflammations, as meningitis, endocarditis, pericarditis, arthritis, etc. In one case of edema of the larynx this organism was responsible. Foà found a case of polyserositis to be due to the same. When a prominent clinician died of nephritis, Massolongo proved that this lesion was due to the pneumococcus. These discoveries were made in the early eighties soon after the discovery of the germ by Fraenkel and Talamon. Other discoveries by the foregoing and other Italian bacteriologists extended our knowledge of the pathogenicity of the germ until it began to appear that this was unlimited. Many of these cases, however, were isolated and of little clinical importance. Guarnieri is said to have been the first to show that the coccus may behave as a true pyogenic. This pathologist also deserves the honor of having been the first to devise a practicable culture technic for the organism. Many animal experiments were made in these early days, and probably the earliest demonstrations of pneumococcus sepsis were simultaneously made. In 1888 Foà and Bonome obtained pneumotoxins by filtration of cultures through a Chamberland filter. It was shown that digitalis and the pneumotoxin antagonized each others' physiological action, so the use of digitalis in pneumonia is not simply that of a chance stimulant. In 1887 Biondi made the first attempts at serotherapy and immunotherapy in pneumococcus pathology. In laboratory animals these efforts were successful. The first antiserum was made by Merck from Pane's formula.

Spanish Influenza in 1853.

In *El Siglo Medico* for October 19 Dr. Cravajal gives an account of an epidemic of influenza which appeared in the province of Caceres in 1853 and was described by an eye-witness in a current medical periodical. This author also witnessed a former outbreak in 1837 and draws comparisons between the two. The phenomena were practically identical save that the older epidemic was the more virulent. The disease picture was as characteristic for the two epidemics as it is in two epidemics of measles or smallpox. The author saw in both episodes the triad of types, thoracic, nervous, and abdominal. The worst sufferers were individuals already affected with respiratory diseases and invalids in general. So complete was the resemblance in all respects between the two episodes and the present one that the author or editor does not see fit to go into particulars about the death rate and fatalities. The "greater malignancy" of one epidemic suggests naturally a considerable percentage of virulent cases, but the complication of pneumonia is not mentioned, at least by the reviewer. It seems quite obvious that severe bronchopneumonias may be present in some and absent in other epidemics.

The Pathology of Influenzal Pneumonia.

Probably influenza has been studied in the past six months more closely than ever before, yet it is evident that a great deal remains to be learned concerning the malady. The pathological findings are of a distinctive character. Dr. John J. Mackenzie contributes to the *Dominion Medical Monthly* for December, 1918, observations on the pathology of influenza in the present epidemic. The cases observed were those of pneumonia following influenza, fourteen autopsies being made. The main

and most important feature of the findings was that the whole anatomical picture, whether gross or microscopic, is different from an ordinary lobar pneumonia, and Mackenzie states that "after a few post-mortem examinations one gets the impression of a characteristic picture which enables one to recognize at once an influenza pneumonia on the autopsy table." Speculating as to what might happen to lungs in this state in those instances in which recovery takes place, the author is of the opinion that the conditions are not favorable to the resolution which follows lobar pneumonia. When recovery takes place from the early stages it is probable no serious damage will be done to the lung tissue. When, however, the disease progresses to the more advanced conditions, one must expect more or less permanent damage to lungs. It would seem then that pathologically influenzal pneumonia, if not a disease *sui generis*, is at least so profoundly modified by the infection of influenza that it presents characteristics unlike those of any other form of pneumonia.

News of the Week.

Influenza Increases.—Reports coming in from various sections of the country show that in some localities there has been an exacerbation of the influenza epidemic. It is said that the disease is as prevalent in Michigan as in the earlier weeks of the epidemic. Baltimore is also threatened with a serious outbreak, there having been 344 cases reported for the week ending December 22. There was a slight increase in the number of cases reported to the New York City Health Department during the week, though not sufficient to be considered a recurrence of the epidemic. The usual death rate from influenza and pneumonia at this time of the year in New York City is about 13 per 10,000 population. For the week ended December 22 it was 14.75 and for the previous three weeks 15.95, 14 and 14.18 respectively.

Influenza in Central America.—Advices from San Salvador report that influenza is prevalent in that country. The sanitary arrangements for the cities have been taken over by doctors from the United States.

To Help Alaska Fight Influenza.—A joint resolution was introduced into Congress, on December 21, by Senator Jones of Washington requesting an appropriation of $200,000 for the relief of hundreds of indigent natives suffering from influenza in Alaska.

Physicians Engaged in Industrial Practice.—Dr. Francis D. Patterson, Chief of the Division of Industrial Hygiene and Engineering, Department of Labor and Industry, Harrisburg, Pa., is desirous of obtaining a complete list of all physicians engaged in the practice of industrial medicine. It is the practice of the Department to hold semi-annual conferences of Industrial Physicians. The next one is to be held early in 1919, and it is therefore desirable to have the names and addresses of all Industrial Physicians and Surgeons in hand as soon as possible after January 1, 1919.

Germany to Educate Illegitimate Children.—Germany recognizes the rights of illegitimate children, of which she is reported to have 200,000. These children are to be educated at the expense of the State.

Medical Unit for Turkey.—A medical unit of 25 doctors and 50 nurses, which is part of the commission of 250 trained men and women to be sent to Asia Minor for reconstruction and rehabilitation work, will sail for Turkey early in January. This is a part of the work undertaken by the American Committee for relief in the near East, which aims to bring a broken people back to their devastated homes, restore their self confidence, their morale, and their faith and secure them against barbarous persecutors. Dr. George H. Washburn of Boston heads the unit.

Dismiss Indictment against Doctor.—Federal Judge Knox has dismissed the indictment against Dr. Nathaniel Blitzer, Chairman of Local Draft Board 98, who was charged with irregularities in connection with the enforcement of the Selective Draft Law.

Dr. Harry H. Bard has been reelected city physician of Pittsfield, Mass.

Dr. Ralph Herz who has been resident physicient and pathologist of the Metropolitan Hospital on Blackwell's Island has left for Rochester, Minn., to become a member of the clinic of the Mayo brothers.

Charitable Bequest.—The will of Stacey Richmond bequeathes $5,000 to the Staten Island Hospital.

Retirement of Professor Emilius C. Dudley.—The faculty of the Medical School of Northwestern University, Evanston, Illinois, gave a dinner at the Hotel La Salle, Chicago, on December 12, in honor of Professor Emilius C. Dudley, who is retiring from the chair of gynecology after 37 years of work. Many colleagues and friends of Dr. Dudley were there and several speakers both from the faculty and trustees bore witness to his great contribution to the development of modern medicine and the affectionate regard in which he was held. Dr. Wm. E. Quine dwelt especially on Dr. Dudley's relation to medical literature. He told of the latter's coming to Chicago in 1875 and his starting the little medical publication known as the *Chicago Medical Review*. Dr. Dudley's first contribution to medical literature was the invention of the word "Trachelorrhaphy," in 1878. This was followed 20 years later by "The Principles and Practice of Gynecology." In general, Dr. Quine declared, the writings of Dr. Dudley are characterized by compactness and directness. There is no suggestion of inflation, but always a real contribution. Dr. Dudley has written infrequently but never without something to say. In thanking his friends for their expressions of regard Dr. Dudley in reminiscent mood gave an interesting résumé of his associations with some of the great pioneers in medicine and surgery during the last quarter of the 19th century.

Influenza in South Sea Islands.—A despatch to the *Associated Press* reports that fully one-seventh of the population of Papeete, the most important of the Society Islands, has succumbed to influenza. The deaths have been so numerous that it has been impossible to bury the victims, so great pyres have been constructed where the bodies are consigned to

the flames. Attempts to keep the epidemic from spreading have failed. It has now reached the Island of Morea where there are no doctors and it is exacting enormous toll.

Boston to Use Influenza Serum.—The Boston Health authorities have decided to treat influenza-pneumonia patients with blood serum taken from those who have been cured of the disease. Dr. W. C. Woodward, City Health Commissioner, has issued a call asking persons who have recovered and are willing to give their blood for this purpose to register at the Health Department. While Boston is suffering from a recurrence of the epidemic, officials point to the low death rate as indicating that the present outbreak is not as serious as the previous epidemic and they believe that many cases reported as influenza are merely colds. A report to the Massachusetts State Board of Health on December 26 showed 778 new cases in the State during the preceding forty-eight hours. Providence, R. I., and Block Island also report recurrences of the influenza outbreak. The health authorities of Providence have called a conference of physicians to consider methods of dealing with the situation.

Needs of New York Hospitals.—As in past years the collections taken up in the churches of the city on the last Saturday and Sunday of the year were for the United Hospital Fund which is shared by forty-six hospitals which give free service to the poor. A much larger contribution than usual has been asked owing to the increased cost of maintenance due to war conditions. The war has so multiplied the expenses of the hospitals that thirty-six of the forty-six hospitals belonging to the organization show a deficit of $391,341 for the year. In pointing out the needs of the New York hospitals, Frederick D. Greene, the secretary of the United Hospital Fund, states that only one person in ten needing hospital treatment gets it. In this respect New York is far behind London. For contagious diseases alone, London had before the war six times as many hospital beds as New York.

Viennese Suffer from Lack of Food.—The Department of Health of Vienna has just issued a report showing that as the result of lack of food large numbers of adults have lost on an average of thirty-eight pounds; even the wealthy have lost an average of twenty-five pounds. The number of deaths has risen appallingly, the city of Vienna registering 46,131 last year against 33,268 in 1914. Every fourth death within the city is now due to tuberculosis, which has assumed proportions that cause the gravest alarm. Official reports on post mortem examinations say that 24 to 30 per cent. of the deaths have been due to starvation. Out of 56,800 children examined by the medical authorities during the year only 4,637 were found in a healthy condition. The average weight of children between ten and sixteen years of age was only 77 pounds, whereas the normal average should be ninety-five pounds. Another medical survey shows that out of every 1,000 children 491 suffer from general debility, 137 from anemia, 90 from catarrh of the lungs, 76 from bronchitis, 23 from heart disease, and 182 from malnutrition. The State Sick Fund for the City of Vienna reports that the number of patients last year was 74,600 compared with 54,200 in 1914. The majority of these cases were caused by stomach and intestinal disorders owing to insufficient food.

Provide Milk for Babies.—The East Side Citizens' Relief Committee of New York has developed plans to provide milk for starving babies. Distribution of milk will be made through the various settlement houses. A legislative committee has been appointed to see to the framing of new laws to prevent babies starving in the future because of price manipulations.

Definition of Diagnosis Puzzles Court.—The Magistrate of the Long Island City Police Court deferred action in the case of a druggist charged with having practised medicine without a license, in order to have time to consider the definition of "diagnosis." A woman went to the man's drug store complaining of pain under her right shoulder, for which she was advised to go home, apply a mustard plaster, go to bed, and on getting up paint the sore spot with iodine. She returned two days later with the pain still there. The druggist told her she had pleurisy and gave her a brown liquid with directions for taking. The druggist admits having given this advice but denies having made a diagnosis. Several physicians called in to testify differed in regard to the definition of diagnosis, one stating that a diagnosis was a determination of diseased conditions by the symptoms that were apparent and holding that a physical examination was necessary, while another stated that a physical examination was not necessary.

Sentenced for Selling Spurious Aspirin—Jose Kukay, owner of the Verandah Chemical Company, which manufactured what it stated was aspirin, in Brooklyn, was convicted a few days ago before Magistrate Dodd of a violation of the Sanitary Code and sentenced to an indeterminate term of not more than three years in the penitentiary and a fine of $500. The "asperin" manufactured and sold by him was analyzed by the Department of Health and found to consist very largely of talcum powder.

Medical Society Elections.—The Kent County (R. I.) Medical Society, at its annual meeting held in Arctic recently, elected the following officers for the ensuing year: *President*, Dr. J. A. Mack; *Vice-President*, Dr. F. Bailey Smith; *Secretary*, Dr. Benjamin F. Tefft, Jr.; *Treasurer*, Dr. F. Bailey Smith.

The Visiting Nurse Association of North Adams, Mass., at its annual meeting held on December 17, elected the following officers for the ensuing year: *President*, Dr. Martin M. Brown; *Vice-President*, Dr. D. J. Caldwell; *Secretary*, William B. Brown; *Treasurer*, Mrs. P. J. Ashe.

The Douglas County (Minn.) Medical Society, at its annual meeting held in Superior, December 12, elected the following officers for the ensuing year: *President*, Dr. A. J. Hovde; *Vice-President*, Dr. H. L. Sarvela; *Secretary and Treasurer*, Dr. J. Baird; *Censors*, Dr. C. H. Mason and Dr. G. Saunders.

The Denton County (Texas) Medical Society, at its annual meeting held in Denton recently, elected the following officers for the ensuing year: *President*, Dr. J. C. Hooper; *Vice-President*, Dr. T. C. Dobbins; *Secretary-Treasurer*, Dr. Martha M. Crofut; *Censor*, Dr. D. Hinkson of Argyle.

The Laurens County (Ga.) Medical Society,

at its annual meeting held December 22, elected the following officers: *President*, Dr. J. J. Barton; *Vice-President*, Dr. A. T. Coleman, Cadwell; *Secretary and Treasurer*, Dr. J. H. Moore; *Board of Censors*, Dr. J. E. New, Dexter; Dr. C. G. Moye, Brewton; Dr. W. R. Brigham, Dublin; *Public Health Committee*, Dr. J. L. Weddington, chairman; Dr. A. T. Coleman, Cadwell; Dr. C. G. Moye, Brewton; *Programs and Scientific Matters*, Dr. E. B. Claxton, chairman; Dr. W. R. Brigham, Dr. H. L. Montford.

THE BIBB COUNTY (GA.) MEDICAL SOCIETY, at its annual meeting held at Macon on December 17, elected the following officers: *President*, Dr. T. D. Walker, Jr.; *Vice-President*, Dr. A. T. Kemp; *Secretary and Treasurer*, C. C. Cleghorn; *Librarian*, Dr. T. E. Blackshear; *Delegates to the State Convention*, Dr. O. H. Weaver and Dr. C. H. Richardson; *Alternates*, Dr. W. J. Little and Dr. T. E. Rogers.

THE FULTON COUNTY (GA.) MEDICAL SOCIETY, at its meeting on December 19, elected the following officers: *President*, Dr. E. C. Thrash; *Vice-President*, Dr. W. B. Emery; *Secretary and Treasurer*, Dr. E. C. Merritt; *Member of Board of Censors*, Dr. Marion Benson.

Dr. Tanner, who attracted a large share of public attention some years ago by his feats of fasting, died in San Diego on December 28 at the age of 91 years, after an illness of a year's duration. He claimed that the practice of fasting occasionally for several weeks at a stretch would ensure health and longevity. That or an inherent strength of constitution seemed to be effective in his case.

Obituary Notes.—Dr. HENRY KIP, a graduate of the College of Physicians and Surgeons, New York, in 1877, died of pneumonia at his home in Paterson, N. J., on December 23, aged 66 years.

Dr. ROBERT NEWCOMB MCHENRY, of Millville, N. J., died at Philadelphia on December 17 at the age of 29 years. He was Coroner-elect of Cumberland County. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1912.

Dr. JOSEPH S. GENTILE of Chicago, a graduate of the Chicago College of Medicine and Surgery, in 1913, aged 33 years, died, on December 15, from a bullet wound inflicted by a patient supposed to be delirious from influenza.

Dr. WILLIAM TOWNSEND VANVRENDENBURG of New Brighton, Staten Island, a graduate of the College of Physicians and Surgeons, New York, in 1881, died at the Home for Incurables, after a long illness, on December 22.

Dr. GEORGE BANEY WOLFE, a member of the staff of the Sheppard-Pratt Hospital, was shot and instantly killed in the office of the institution on December 21. He was a graduate of Johns Hopkins University in 1912, and was 33 years of age.

Dr. MATTHEW B. DUBOIS, a graduate of the College of Physicians and Surgeons, New York, in 1868, died after a long illness at his home in New York on December 29, aged 78 years.

Dr. EDWIN E. JONES of Colebrook, N. H., was instantly killed in an automobile accident on December 28. Dr. Jones was 48 years of age, a graduate of Dartmouth Medical college, in 1894, and founder of the Colebrook Hospital.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

MEDICAL TREATMENT OF RETURNED SOLDIERS—UNWANTED IMMIGRANTS—INFLUENZA IN DUBLIN—RETURN OF THE DOCTORS WITH THE ARMY—DEATH OF MR. NOTTIDGE C. MACNAMARA.

LONDON, Dec. 12, 1918.

IN the natural course of events the majority of returned soldiers in need of medical advice and treatment have come under the aegis of the Ministry of Pensions. While the war was on the sick soldiers were roughly divided into two classes:—those temporarily sick but believed to be fit for further service who were on treatment at the various military institutions to which their conditions had allocated them; and those who were retired from the army on physical grounds being entitled to pensions and who came within the jurisdiction of the Pension Department. This department has always attempted to perform its implied promise that any man who had suffered from one of the diseases of the war should be brought before a medical tribunal properly selected and should have his pension allotted in the circumstances most likely to improve the disablement or afford him chances of cure. In all methods of improvement as well as in all methods of cure medicine and surgery have advanced with enormous strides during the war, new knowledge being founded on the experience of a struggle carried on unceasingly for over four years in the hottest, the coldest, the driest, the wettest, the healthiest and the most pestilential, the richest and the poorest, districts of the known world. Every clime has brought its lesson, for change of environment has affected the diagnosis and treatment of conditions with which we were previously but half familiar. Further, the medical professions of the Allied Nations, by interchange of information on every conceivable subject, have joined in a marvelous symposium of pathological learning and endeavor. It is now hoped and expected that all the pensioners will obtain full benefit of this learning, will receive expert examination and advice, and be recompensed in accordance to their claims by persons who are scientifically competent to evaluate them. Fortunately the Royal Army Medical Corps has already taken anticipatory steps toward some comprehensive policy. It is their officers who have seen malaria in all its forms, dysentery in all its varieties, cardiac disorders produced or aggravated by military service, special military conditions like trench fever, shell shock and a host of other neurological troubles, and special naval conditions like hideous burns. For some time now the Army Medical Staff has set up special hospitals at various centers, and for these hospitals prompt steps will be taken to procure the assistance of medical advisers, learned in each particular direction, so that during the course of demobilization the pensioner may be drafted with the least friction and trouble to the institution best suited to his case. For six months after the war, beginning with this week, Colonel A. L. Webb, Assistant Director General of the Army Medical Staff, will take over the program thus outlined, and will bring under one head the activities

of his own department and those of the Ministry of Pensions. That full justice should be done to those who have fought for their country and suffered bitterly in fighting is the determination of the whole country, and that this ideal forms a part of the election address of every candidate for the new Parliament is only an expression of the view held by all. Colonel Webb has been a most competent assistant to Surgeon General Goodwin, the Director General of the Army Medical Service, and in his hands a very difficult piece of organization stands good chances of success.

At the end of the eighteenth century, and about twenty years after the celebrated discoverer, Captain Cook, had explored the east coast of Australia, the British Government founded at Port Jackson a penal settlement. Tasmania, a hundred years ago known as Van Diemen's Land, was similarly treated, and in the early history of New South Wales the reception of British convicts played a large part. But in the first forty years of civilized life Australia, emerging from a military colonization to an infant commonwealth, made such strides that the need for bond labor disappeared, and the determination not to play the host to such undesirable immigrants was made good. Is some such analogous determination with regard to tuberculosis about to take place? And if so, can reasons of equivalent force be put forward? The British dependency now in question is South Africa, where the public proposals with regard to the admission of ex-soldiers, who may be tuberculous subjects, have been warmly criticized. When it was generally believed that the Union Government intended to waive the regulation controlling the entry of tuberculous immigrants in favor of ex-soldiers, the feeling grew so high that a semi-official *dementi* had to be issued, but it stands to reason that South Africa must be prepared to deal with her own tuberculous veterans. And to medical men a resolution to go further, with proper precautions, would certainly commend itself. Except in the caustic humor of the late Samuel Butler, disease cannot be compared to sin and treated as sin, and what Australia did in 1839 in respect to convicts is not an example to be followed by South Africa eighty years later in respect of tuberculous subjects. South Africa is possessed of climate and of opportunities that make the intelligent treatment of tuberculous subjects successful and enable that treatment to be conducted without risk to others, and it is to be hoped that the policy of exclusion will not be persevered in, or, at any rate, will not be insisted upon before the possibility of providing proper hygienic precautions has been discussed. There is a whole political party in South Africa which is opposed to all immigration of any kind, and the suggested introduction of a large mass of tuberculous ex-soldiers and ex-sailors, against whose immigration reasonable protest can on the surface be made, will much strengthen the hands of this party. Medicine involved in politics is apt to come off second best, but it is to be hoped that the Union Government will come to no hasty decision.

The influenza epidemic has surged up, dropped, risen again, and done everything but definitely disappear during the past fortnight. In some localities hitherto unattacked it has just made its first appearance; other localities which from previous attacks should have been rendered immune are again registering many cases. But to Dublin its attachment has been faithful. The medical officer of health of the city of Dublin, Sir Charles Cameron, has now stated that a decline in the epidemic has virtually begun, and certainly the number of deaths in Dublin from influenza last week went to support his statement—or were the origin of it. There were no one knows exactly how many deaths—43 is the official estimate—because different doctors had different standards of diagnosis, but the group of conditions signalized by rapid attacks of pneumonia apparently caused ten deaths less than in the previous fortnight. The public health of Dublin, as of Belfast, remains highly discreditable to the authorities, and the fault entirely lies with them and a supine public and not with the hard-worked and capable executive officers. It is probable that in both the great Irish cities the influenza is now subsiding, as is happening in great English centers like London and Manchester. The health authorities in Manchester are now confident that they have secured the upper hand of the epidemic, which has been devastating the city for more than a month. The deaths in the first week of December were 243, but the total is 144 fewer than in the week before. At Bristol in the same week the deaths fell to 84, after an average for the previous month of 100.

It is admitted on all hands that as many medical men as can be spared promptly from their temporary military duties should be returned to civilian practice. No one knows the cause of the delay that is taking place, unless it be that, Parliament being prorogued for the general election, all the ministers concerned are absent in their constituencies on electioneering business. A great many people have deplored the necessity, if necessity there was, of holding a general election, and certainly the dearth of doctors lends point to the view that only the profoundest national necessity ought to have arrested the domestic business of the country at this moment. None of the civil departments hold any view save that it is imperative that doctors should be returned at the first possible moment. The Local Government Board, the Board of Education, and the National Insurance Commission are in agreement here with the War Office probably, and with every other branch of government. The health of the country is on the whole good, despite the ravages of influenza, and even here, smitten though every division of the kingdom has been, the toll of life has been lower than in many other countries. But winter is upon us, bringing with it the usual train of sickness, especially among the old and among women and children, and the sadly depleted ranks of the general practitioner at home look forward with real apprehension to the approaching work. For years these men have done double and treble shifts, and it is due to their devotion that the general health, urban and rural, has been maintained throughout the war at a good level; but they are nearly at the end of their tether, and it is a cruel situation that relief, abundant relief, is available, and that only official delay precludes it from materializing to a great extent. This is not to say that doctors, and infinitely more doctors than have any place on the regular military establishment, are not required by the army. We still have millions of men under arms and a large percentage of sick and wounded in the military establishments. With the cessation of war

the acute rushes of work no longer occur; but a vast military population remains, and some of it under quite unfavorable conditions, whose medical needs must be cared for; but having regard to the excellent discipline which now prevails in a military organization tried by more than four years of war, there should be no difficulty in promptly deciding how many civilian medical men must be retained with the colors, and how many can be spared to take up the increasing burden of civilian practice.

The death has occurred of Mr. N. C. Macnamara at the great age of 86. He was a consulting surgeon of wide repute in his day, and was a learned man outside purely professional subjects. He also made an unusual start by joining as a young man the Indian Medical Service, and remaining for no less than 20 years in that service, so that he was 44 years of age when, on retirement as a surgeon-major, he decided to start in London as a consulting surgeon. While in India he had specialized on diseases of the eye, and when he was appointed general surgeon to the Westminster Hospital he also obtained the post of surgeon to the Westminster Ophthalmic Hospital. He soon obtained office in the Royal College of Surgeons of England, being vice-president in 1893; the presidency in many opinions should have gone to him also. His wide general reading found expression in a book published in his eighty-fourth year entitled "Instinct and Intelligence."

4. The Constipation Treatment of Pneumonia.—Edward E. Cornwall states that for the past six years he has employed the "constipation treatment' of pneumonia and that his belief in its value has been strengthened by his own experience and the testimony of others. This treatment consists of letting the bowels alone unless special conditions arise which call for the use of artificial evacuants; for instance, if no bowel movement has taken place within twenty-four hours of the time when the patient comes under observation and the disease is in its early stage and the heart in good condition, a mild laxative or enema is given; or, if marked tympanites developes, if patient complains of a sense of fullness in the rectum, a simple anema is given; and two days after defervescence an enema is regularly given if necessary. An important feature of the treatment is the regulation of the diet. The quantity of food is reduced below the health ration and its nature must he such that it will change the intestinal flora from malign to benign types. Articles of food which constitute culture media favorable to the development of swallowed pneumococci and indigenous saprophytic bacteria must be excluded from the diet, and those which constitute media favorable to the growth of benign acidophilic bacteria must be included. The saline balance in the diet must be preserved and the calcium deficiency provided against; proper rations of alkalies and the necessary vitamines and water must be supplied. In general, the food must be such as will leave little undigested residue and discourage the activity of the saprophytic bacteria, in which case large fecal accumulations cannot well take place and the author gives a dietetic prescription to meet these requirements. Another feature of the treatment indicated is the stimulation of the heart. This stimulation is not begun until found necessary and care is taken to avoid overstimulation. Strychnine, strophanthus or digitalis, and caffeine are used. First, strychnine sulphate in doses of 1/60 grain every four hours. If more stimulation is needed, one and a half to three minims of tincture of strophanthus is added every four hours—or, if the tincture is not well borne or a more powerful effect required, intramuscular injections of 1/1000 to 1/500 grain of strophanthin are given every four hours. If still more stimulation is required, caffeine citrate or caffeine and sodium benzoate is given every four hours, and perhaps the dose of strychnine is increased to 1/30 grain. If found necessary, the dose of strophanthin may be increased temporarily to 1/250 grain every four hours, and in sudden and severe cardiac failure 1/100 grain of strophanthin is given intramuscularly or intravenously; in the latter case, however, no more strophanthin must be given for twenty-four hours, although the other drugs may be continued. Alcohol is usually given to alcoholic addicts and to patients advanced in years. In this plan of treatment, a conservative attitude is adopted towards the relief of symptoms. It is recognized that symptoms are evidences of nature's reparative activity and should not necessarily be suppressed; it is also recognized that severe and persistent symptoms may be harmful and therefore require modification. Pain, cough, restlessness and insomnia are relieved by hot poultices, morphine and codeine in small doses; opiates, however, are strictly forbidden in the later stages of the disease and if respiration is embarrassed. Diarrhea, vomiting, and tympanites, which latter rarely occurs during the treatment, are controlled by diet restriction. The author lays particular stress on the avoidance of routine catharsis, and especially the routine administration of calomel and magnesium sulphate, pointing out that magnesium sulphate is a cardiac depressant and kidney irritant after absorption, and that calomel is an irritant to the intestinal mucosa and hepatic tissues. Antipyretics are given only in case of hyperpyrexia. Diuretic and expectorant drugs are not given, and reliance is placed on the diet for modifying the intestinal flora. Two series of cases are cited, each treated in the same hospital, the first extending from May 1, 1906, to January 1, 1913, and the second from January 1, 1913, to July 1, 1918. In the first series of 124 cases artificial evacuants were employed, the mortality being 30.6 per cent. In the second series of 218 cases, when artificial evacuants were not used regularly, the mortality was 18.8 per cent.

3. Comparative Value of Ipecac and Its Alkaloids in Treatment of Intestinal Endamebiasis.—Sidney K. Simon reviews the history of ipecac as a therapeutic remedy since its introduction into Europe in 1648. As a result of the disagreeable effects which often attended its administration, the drug had fallen into almost complete disuse until rescued from oblivion by Sir Patrick Manson and other English observers in the tropics. Investigations into the pharmacology of ipecac were made as far back as 1817 by Pelletier, who believed that the root contained but one alkaloid—emetine. In 1894, Paul and Crownley discovered cephaeline, and subsequently another alkaloid—psychotrin—was identified.

Experiments on the toxic effects of emetine showed that (1) Emetine depresses and may eventually paralyze the heart; (2) It is a powerful gastrointestinal irritant, whether given by mouth of by subcutaneous injection; (3) It causes definite derangement of metabolism characterized by increase in nitrogen loss and an acidosis; (4) While these actions may not be of importance in normal individuals, in pathological states of the circulation, intestinal tract, or metabolism, they may be a very definite source of danger. Moreover it has been shown that the physiological action of cephaeline is closely similar to that of emetine, and both of these alkaloids have failed to remove encysted ameba from the tissues. In view of this, the author became more and more convinced that serious consideration should be given by the profession to a return to the use of the original crude ipecac root, and in 1909 he first employed ipecac in the form of enteric coated pills, with gratifying results. He points out, however, that a careful attention to detail is essential in this method of treatment, and he attributes former prejudice against the administration of the crude ipecac to failure to observe the smaller details of the treatment. He concludes that: (1) Both ipecac and its constituent alkaloidal derivatives, emetine and cephaeline, have been found to act specifically on the vegetative or living forms of the *Endamoeba histolytica*. (2) The crude ipecac root in doses sufficient completely to destroy the infecting organisms is never toxic. (3) Both emetine and cephaeline frequently exhibit toxic properties in an average dosage of from 0.5 to 1 grain daily over a limited period. (4) The alkaloids alone are ineffective within safe limits of dosage in destroying the encysted forms of the *Endamœba histolytica*. (5) The entire ipecac root, when employed under proper conditions, not only destroys the vegetative endameba but the encysted forms as well, and thereby prevents recurrences or relapses of the infection.

4. A Case of Repeated Cessation of the Heart Beat.—E. P. Poulton and H. M. Stewart report a case of repeated stoppage of the heart beat with fatal result. The patient, a man of 67 years of age, had been healthy all his life and had been accustomed to take lots of exercise. There was no history of specific disease. On March 13, he complained of giddy attacks and pulse on one occasion was 30. He stayed in bed for two or three days and got up feeling quite well, though he was having short fainting attacks each day. On March 25th at 2.30 p. m. he began having repeated fainting attacks until 4.30, and again from 5.30 to 7.30. He then got some sleep, but the attacks recommenced at 10 p. m. and continued almost without intermission until his death on the afternoon of March 28. During these attacks the heart stopped beating, and all attempts to interrupt the cycle were without effect. During the period of unconsciousness, the most noticeable feature about the case was the rapid deep breathing, which the authors state was more marked than they had ever observed in any other pathological condition. The length of the cycle was from 115 to 125 seconds, and roughly it might be said that during every two minutes the pulse completely stopped for 40 seconds, during which time no beat of the heart was audible under the stethoscope and there was no sound suggestive of auricular beats, nor was any venous pulsation observed in the neck. No polygraph tracing could be obtained. In this case there was no obvious abnormality in the heart. Postmortem examination showed the lungs congested and edematous; atheroma in aorta; hypertrophy in both ventricles; mottled heart muscle, and moderate degree of fibrosis was suspected; coronary arteries were atheromatous but patent; aortic and mitral valves were slightly thickened. The brain substance looked healthy; vertebral, basillar, internal carotid and cerebral arteries were all atheromatous. Microscopic examination of sections of the medulla at the middle and upper part of the vagus nucleus showed vacuolation of some of the cells and apparent chromatolysis with, occasionally, eccentric nucleus. Numerous small hemorrhages were found throughout the sections, which were probably secondary to the repeated asphyxial periods. Sections were also examined of the lower part of the medulla and of the vagus nerve trunk; these showed no abnormality or sign of degeneration. The authors call attention particularly to the enormously increased respiration observed in this case during the attacks. This was due presumably to stasis of CO_2 in the respiratory centers associated with a lack of oxygen. The rapid onset of dyspnea suggested a local action on the centers and it may well be, as Haldane and Douglas have suggested, that the lack of oxygen acts by forming lactic acid locally in the respiratory center. The authors refer to Neuburger and Edinger's case as a basis of comparison.

5. The Spacing of Injections in the Maintenance of a Pneumothorax.—Claude Lillingston points out that since pneumothorax was started in England in 1910 there has been no great teaching center or standard work from which a beginner could learn or turn for help in difficult cases. Dr. Clive Riviere's book has therefore met a want. The effects of inadequate teaching are particularly evident with regard to the spacing of refills and the total duration of the treatment, and as a warning against too long intervals between refills the author gives the history of one of his own cases. In the case in question, a few days after the ninth injection an acute intercurrent infection sent the temperature up and it was thought best at this critical stage to defer injections for fourteen days, when the temperature was practically normal again. It was then found, however, that the lung had become adherent to the chest wall. In spite of frequent injections of gas, when as high a pressure as + 16 cm. of water was created, the adhesions did not give way and even the development of a pleural effusion several weeks later failed to compress the lower half of the lung. The author therefore emphasizes the importance of frequent refills, the common mistake being to err in the opposite direction. He states that in his ten years' experience, he cannot remember a single case either under his own care or that of his colleagues, in which refills were given too frequently.

3. Some Reflections on Cardiac Conditions in Soldiers.—R. O. Moon points out that while on the one hand the war has shown the strength of the heart, it has also shown its weakness. As was to be expected, the number of cases with definite organic heart lesions is comparatively small, since such recruits would hardly be admitted into the army. Instances have occurred, however, in which a soldier with a serious cardiac lesion has been able to perform an extraordinary amount of work and to carry on satisfactorily for a considerable length of time. All valvular lesions—mitral or aortic—when of degenerative, arteriosclerotic origin, are unfitted for active service, French writers being of the opinion that mitral stenosis shows least resistance to active service conditions. The great majority of cardiac cases in military hospitals were invalided with a variety of symptoms, such as shortness of breath on the march, faint feelings, giddiness, and especially a general sense

of exhaustion, with, occasionally, nocturnal palpitations; but complaint of actual pain was infrequent. One might term many such cases "subnormal" hearts. The usual physical signs are rapid pulse, a diffuse slapping impulse, and at times an indefinite short systolic murmur at the apex, which has little resemblance to a true organic mitral murmur. Many of these patients have suffered in the past from rheumatism, diphtheria, or frequent attacks of influenza, or they have had trench fever or some indefinite febrile disorder during the war. (The author is of opinion that these last named affections do quite definitely impair the efficiency of the myocardium.) Doubtless many hearts which give way on active service are intrinsically unsound though they were able to do their ordinary work in civilian life because it involved no particular strain. It is the sudden and unexpected demands made upon them that tell on the nervous system, and this factor it is impossible to estimate beforehand by any mechanical device. The serious effect of emotion upon the heart was noted by Corvisart during the French Revolution and in this war three definite cases of permanent tachycardia of emotional origin have been recorded by French physicians. The author has found that malaria rarely has more than a transitory effect upon the heart; he thinks it probable that when cardiac weakness does occur in malaria, it is due to the dysentery from which the patients have frequently suffered rather than to the malaria; Da Costa gives "prolonged diarrhea" as one of the most frequent causes of the "irritable heart of soldiers." In the author's experience the tachycardia which is so common in soldiers has not often been due to hyperthyroidism. Tobacco he considers a far more potent cause, especially in young soldiers. Arteriosclerosis is fairly common among older men, but is usually due to causes which were in operation before the man entered the army; it is, however, made worse by abuse of alcohol and tobacco and, in the British army, by the excessive meat dietary. A number of observers, and British physicians particularly, have insisted upon the fact that many cases of apparent cardiac disability are not, strictly speaking, cardiac at all; they might be regarded as conditions of "cardiasthenia" on the analogy of neurasthenia. How much is due to a nervous and how much to a muscular affection, however, must be determined by the physician; it is unlikely that mechanical methods will prove of much assistance.

Berliner klinische Wochenschrift.

October 12, 1918.

Operations on the Nerves and the Late Results.—L. Seyberth is rather optimistic and publishes the case records of fifteen patients in whom the nerve was either cleared from a bed of cicatricial tissue or nerve suture in cases of division. The functional results were, generally speaking, satisfactory, with the exception of the cases where an anastomosis of the divided nerve was made with another nerve trunk. Suture of a traumatized nerve gives a much more constant success than might be expected. From his personal results Seyberth is of the opinion that operation should be undertaken in all cases of nerve injury. From the technical viewpoint the writer recommends among other things never to incise a muscle during the interference. If a muscle cannot be retracted either to one side or the other it is better to divide the tendon and thus expose the field of operation. The tendon is afterward sutured and the function of the muscle is perfectly preserved.

The Action of Quinine on the Blood.—F. Johannesohn studies especially the action of quinine given hypodermically to healthy subjects, on the number of red and white cells, and the tenor of the blood in oxydases. The leucopenia created by a prolonged absorption of quinine may attain less than 50 per cent. of the initial figure. After exhibition of the drug has been stopped the normal number becomes rapidly established. But if the treatment is continued sufficiently long, after a leucopenia of several weeks' duration, the number of leucocytes will nevertheless return to the normal. A sort of immunity to the drug is acquired by the leucocytes. It is to be noted that during the quinine leucopenia the digestive or infectious leucocytoses are quite as intense as in an untreated subject. The leucopenia is not the result of a destruction of the leucocytes, because the elimination of nitrogenized bodies of the urine is not increased. The writer admits that only a retention of the leucocytes takes place in certain organs. Studying *in vitro* the inhibition exercised by the salts of quinine on the fermentative process of oxydation, the writer notes that this inhibition is only realized in concentrations such as never occur in the human body. In therapeutic doses quinine is incapable of counteracting the organic oxydases.

Münchener medizinische Wochenschrift.

October 21, 1918.

The First "Trimenon" (Quarter Year).—E. Moro shows by a series of interesting considerations that the first three months of life represent a perfectly characteristic evolutive period, possessing its own physiology and pathology, as well as a peculiar physiognomy. This period is distinguished by the rate of growth in both length and weight which, from the fourth month, offers a sudden drop in the rapidity of the increase by the extreme lability of the digestive junction and by the frequency of certain dermatoses. Rhachitism and spasmophilia are practically nonexistene at this period of life. Apropos of this, the writer limits the hypothesis that calcium should be given to nurslings from the time of birth in sufficient quantity for the needs of the baby during the nursing period. At any rate, the dose, even when small, is sufficient in the majority of cases for the needs of the baby during the first three months. As a practical consequence of these considerations, Moro shows that the minimum time for breast feeding should be at least three months in cases where it cannot be continued for a longer time, as this is the only kind of feeding which is perfectly adapted to this period of great organic frailness.

The Complications of Dysentery and Their Treatment.—Schemensky offers the following conclusions: (1) Articular and muscular rheumatism is an important sequela of dysentery and possesses a particular tenacity, although the pain is bearable. Treatment by polyvalent serum at the dose of 40 c.c. frequently repeated. (2) Cardiac affections are uncommon during dysentery, and when they occur are only temporary. (3) Anemia of the symptomatic type appears after repeated intestinal hemorrhage, and to it is due the weakness, tinnitus aurium, vertigo, vomiting, and gastric disturbances which may persist for a long time after recovery. (4) The edema following dysentery is similar to independent edema observed during the war and due to vascular lesions. (5) The writer insists, from the viewpoint of bacteriology, on the insufficiency of our diagnostic means. The diagnosis is above all clinical and epidemiological.

Deutsche medizinische Wochenschrift.

October 17, 1918.

The Treatment of Diphtheria with Plain Horse Serum.—H. Bonhoff has undertaken to reply to the conclusions arrived at by Bingel, who made a comparative study of the results obtained by antidiphtheritic serum and those of plain horse serum and came to the conclusion that they were identical in effect. Ordinary antidiphtheritic serum, therefore, does not act on account of its antitoxin content but merely in its quality of serum. Bonhoff criticizes Bingel's reasoning, and, taking the same statistics, he makes them show quite the opposite conclusions. He likewise recalls the results obtained by animal experiment which proves that the serum acts as an antitoxic agent. Laboratory experiments have up to date only accentuated the analogy between the reactions of the human body in disease and those of animals used in experimental work. It is therefore permissible to draw conclusions from animal experiments which possess both a clinical and therapeutic value. The position taken by Bingel, Bonhoff holds, is to be considered as nefarious and even dangerous from the viewpoint of epidemiology and treatment.

A Case of Mitral Lesion with Cardiac Asthenia, the Ventricular Weakness Being Demonstrable by the Venous Pulse.—R. Ohm records the case of a patient in whom the diagnosis of a mitral lesion appeared cer-

tain. By the use of the volumetric phlebograph which the writer has invented he came to the conclusion that there was an asthenia of the right ventricle, as this should give a diastonc wave "en plateau" on the phlebogram. It is to be remarked that the case is not sufficiently elucidated from the viewpoint of the diagnosis because in point of fact the electrocardiographic tracings reveal a total bradycardia of 46–42 to the minute, for which the writer offers no explanation. As to the change in the venous pulse, it enters into the type of diastolic stasis described long since by Bard (of Geneva) who regarded it as a characteristic evidence of lesions of the left heart.

The Serodiagnosis of Syphilis.—F. Lesser continues his studies on Meinicke's reaction. Less complicated than the Wassermann, it is of equal specificity. As to the drawbacks of this reaction and doubts arising in the interpretation of results, they are the same as for other reactions.

Wiener medizinische Wochenschrift.

October 12, 1918.

The Care of the Injured in the War and Social Hygiene.—J. Kaup offers some details on the organization of these services in Austria. The recruiting in civil installations is very much more considerable in Austria than in Germany. Reserve Hospital No. 11 at Vienna was able to send back 75 per cent. of the 24,000 wounded soldiers who were treated there to the army. These men were treated for contractures, which represented 33.3 per cent. of the cases, 25 per cent. were for paralyses, and a small fraction were bone lesions.

Le Progres Médical.

November 2, 1918.

Prevention of Grippe by Quinine and Arsenic.—Professor Garin of the Medical School of Lyon, in watching an epidemic of influenza at Briançon in which soldiers and civilians were alike attacked, was struck with an apparent immunity enjoyed by the paludic subjects. These men were under antipaludic treatment by both quinine and arsenic. He next sent out a questionnaire to 90 hospitals and sections for paludics. The queries were: "Did you have epidemic grippe in your locality this year?" "Did your paludics suffer from grippe—and if so what was the percentage attacked and the mortality?" "Did grippe appear to be less severe in your locality than in others near by?" "If your formation was exempt, to what do you attribute this fact?" From the 90 addressed the author received answers from 46 and of the latter number 28 were practicable for use. Of these 28, all but 5 replies appeared to justify the author's stand. In 17 of these hospital units visited by influenza not a single paludic contracted the disease; while in 6 others the immunity was relative, not absolute. The immunity had been explained in some of the hospitals by the use of quinine alone or quinine and arsenic in combination. Others attributed the immunity to isolation, pure air, and the use of gomenolised oil respectively. The 5 negative experiences contrasted in toto with these positive finds, for not only was there no immunity in malarial subjects but several deaths occurred. However, although the disease ran a severe course in those attacked, the percentage of victims was for some reason very small and could hardly be termed epidemic at all. Why should a few contract the disease and some of these die while so many escaped the disease? The author made an attempt to learn how much quinine and arsenic was used, but no data were forthcoming.. There is a second practical question bound up in that of prophylaxis, for the author made use of his immune paludics to nurse the grippe patients. The daily prophylactic dose of quinine is 3 cgm. and of arrhenal 0.05 gm.

Correspondenz-Blatt für Schweizer Aerzte.

October 5, 1918

The Influenza Epidemic.—Bircher devoted his holiday to a study of the epidemic in various places. He could not convince himself that Pfeiffer's bacillus caused anything but a secondary infection. Many cases bore on the face the stamp of streptococcus sepsis of virulent type. All bacteria found were apparently only secondary and symbiotic offenders. In regard to meteorologic conditions no summer was so hot, so dusty and droughty in the memory of the physicians. Overwork was a predisposing factor, as illustrated in callings like medicine and munition work. The neurotic seemed, however, to enjoy a slight immunity. About one half of the hospital patients had pneumonia. No age was exempt. The young showed more resistance than the middleaged, while over 50 there were no severe cases. The greatest incidence was in army orderlies at the age period 35-45, few escaping. This fact speaks for the contagion of the epidemic on protracted exposure. Some pneumonia was fulminant, as one case which began in the midst of health at 4 P.M. and ended fatally at 10 A.M. the next day. In many others death occurred in 2 or 3 days. In all of these rapid cases cadaveric spots were seen one or two days before death as an uncanny prognostic. In many cases the disease began in the upper lobes and extended rapidly to the lower, besides being mostly bilateral cases. Section showed, however, that in many cases the pneumonic invasion could not alone have caused death, the latter having been due to sepsis. The type of bronchopneumonia resembled that of the Manchurian pneumonic plague or pestous pneumonia. The mortality from pneumonia was about 35 per cent. In recovered cases recovery was tedious. Relapses occurred despite all precautions and were severe and often fatal. In many cases empyema developed. Pregnant women tended to abort, and those confined to develop sepsis locally (para- and perimetritis). Loss of weight was often startling, as much as forty pounds in one week in some patients. Purulent rhinites and otites were not uncommon during convalescence. Tuberculosis was often lighted up. The only remedies to produce results were high doses of electrargol and pneumococcus serum in indicated cases. In a few cases there was a positive Wassermann. Of cardiac stimulants caffeine appeared to be the most dependable. Quinine was of apparent value, even also as a prophylactic in the author's opinion. The author, who is a well-known surgeon, believes that his excursion into internal medicine was of benefit to him. Seeing how little the internist can do in such cases, Bircher says, he goes back gladly to his surgery where one can realize one's power for good or evil.

Hygiea.

September 30, 1918.

Neuritis Puerperalis Traumatica.—Rodhe reports three cases of this affection, which he also terms traumatic maternal birth paralysis. The first was one of forceps delivery, thirty-six hours in labor, child's weight almost 5000 gms. Immediately after delivery there were severe pains in both lower extremities, which soon subsided in the left, but were persistent and chronic on the right side. Even during gestation there was a sensorimotor paresis in the right lower limb, so that the puerperal affection was merely an epiphenomenon. The case yielded to time or treatment and the patient bore another child without neuritic happening. In the second patient, labor had been arrested for twelve hours and pain in the extremities developed when labor pains were resumed. Labor lasted twenty-four hours more, and was then ended by perforation. One week after delivery both lower extremities were almost completely paralyzed, but after that period there was resolution which lasted much longer on one side—two months on the right. At this juncture the woman was examined and the right leg was found atrophied, with both motor and sensory disturbances in the peroneal distribution. Six months after delivery she was pronounced well. In the third patient the symptoms were in evidence some while before delivery, the right leg going to sleep at intervals. After labor this symptom was increased. The labor was normal but slightly prolonged and the child was large. The symptoms set in directly after labor, and for the first three weeks after delivery she was hardly able to move the limb. After some improvement was apparent under treatment the patient failed to appear and the fate of her paralysis remains unknown.

Book Reviews.

A Treatise on Clinical Medicine. By William Hanna Thomson, M.D., LL.D., Physician to the Roosevelt Hospital; Consulting Physician to the New York State Manhattan Hospitals for the Insane, and to the New York Red Cross Hospital; formerly Professor of the Practice of Medicine and of the Diseases of the Nervous System in the New York University Medical College; Ex-President of the New York Academy of Medicine, etc. Second edition; revised. Price, $5.50 net. Philadelphia: W. B. Saunders Co., 1918.

A reading of Dr. Thomson's book assures us that he was a master practitioner, trained in the bedside school, over which there has been no improvement since Hippocrates founded it. His remarks on symptomatology are especially good and can be recommended to those who hurry anxiously from the sick-room to the laboratory in search of a diagnosis. After a discussion of symptoms and remedies, Thomson devotes 170 pages to infections and 410 to diseases of special tissues or organs. Much there is of value in this, the fruits of a lifetime's experience. We could have wished that the author had not been so dogmatic about points not proved yet or where the weight of authority is against him and that he had fortified his own apparently somewhat tenuous knowledge of certain subjects by a recourse to the literature. As illustration of the former point we mention his treatment of influenza (page 114) and of the latter point the one page devoted to general paresis. The section on drug habits is very poor. The only discussion of treatment is the advice to recover from a drug habit by getting away from it. As well discuss the treatment of syphilis by saying: Don't get it in the first place, but if you do, get rid of it. But it is easy enough to pick out flaws in a work of this kind. With all its defects there is much worth while in the book and there is probably no practitioner who would not find parts of it helpful.

Aids to the Analysis of Food and Drugs. By C. G Moor, M. A. (Cantab.), F. I. C., Capt. 1st London Sanitary Company, R. A. M. C. (T. F.), Public Analyst for the County of Dorset and the Boroughs of Poole and Penzance; and William Partridge, F. I. C., Joint Public Analyst for the County of Dorset, Lecturer on Analysis of Food and Drugs, South-Western Polytechnic, Chelsea. Fourth Edition. Price $1.50. New York: William Wood and Company, 1918.

The analysis of food and drugs does not fall within the duties of the physician; but a brief account of the various adulterants of foods and drugs, with a description of recognized methods of detection and an explanation of the results of the analysis may be of great service. The present little volume contains chapters on: Milk, butter, cheese, starch foods, bread, baking powder, vinegar, tea, coffee, cocoa, pepper, ginger, mustard, spices, honey, sugar, jam, jellies, ice-cream, custard powder, lime and lemon juice, beer, wine, cider, spirits, sausages, oils and fats, tinctures, poisonous metals in foods, commercial disinfectants, soaps, and various pharmacopeial articles. The authorities, regulations, etc., are based on the Pharmacopeia and government orders of Great Britain. The book is small in size, but authoritative, and contains much that may prove of value to the medical man.

Diseases of the Male Urethra, Including Impotence and Sterility. By Irvin S. Koll, B.S., M.D., F.A.C.S., Professor of Genito-Urinary Diseases, Post-Graduate Medical School and Hospital; Associate Genito-Urinary Surgeon, Michael Reese Hospital, Chicago. Illustrated. Price, $3.00. Philadelphia and London: W. B. Saunders Co., 1918.

Despite its importance as a portal for the entrance of infection and the multitude of pathological changes subsequent to its infection, the male urethra has not received commensurate consideration from urological writers. Dr. Koll's contribution is an advance in this direction. After a short anatomical description of the urethra, he rapidly sketches the history of gonorrhea, its bacteriology, pathology, symptomatology, diagnosis, and treatment. The chapter given to urethral stricture classifies that sequel under the following captions: the anatomic, pathologic, and clinical. The divisions and subdivision of these captions are good. In general the author's opinions, advice, therapy, and technique coincide with those of modern urologists. A notable exception is his championship of Warden's conclusions on the bacteriology of the gonococcus. A lengthy quotation from that writer's essay entitled "The Role of the Staphylococcus in Gonorrhea" (*Journal of Infectious Diseases*, Vol. 13, July, 1913) is incorporated in the chapter on bacteriology. Without prejudice to Warden's serious and conscientious studies, attention must be directed to the facts that many bacteriologists hold his views to be nihilistic, and that clinicians do not accept his views that the grouped intracellular diplococci found in urethral pus are most frequently urethral staphylococci. Dr. Koll has succeeded in his efforts toward conciseness, clearness, and simplicity and has presented well chosen and well executed illustrations.

Gynecology. By William P. Graves, A.B., M.D., F.A.C.S.; Professor of Gynecology at Harvard Medical School; Surgeon-in-Chief to the Free Hospital for Women, Brookline; Consulting Physician to the Boston Lying-In Hospital. With 368 halftone and pen drawings by the author and 123 microscopic drawings by Margaret Concree and Ruth Huestis, with 100 of the illustrations in color. Second Edition. Thoroughly revised. Price, $7.75. Philadelphia and London: W. B. Saunders Co., 1918.

This work is intended for use as a textbook as well as a general reference book of gynecology. For this reason a special classification has been adopted by means of which the subject matter is divided into three distinct parts. However, as this is a second edition it will be unnecessary to explain the general scheme of the book. One feature of this scheme may be emphasized that in Part I the physiology of the pelvic organs and the relationship of gynecology to the general organism are dealt with.

The entire matter has been thoroughly revised and brought into conformity with the latest knowledge and most recent views. For example, that portion in which the relationship of gynecology to the internal secretions has been almost wholly rewritten and enlarged. Of especial interest is the discussion concerning the value of radium in the treatment of cancerous and non-malignant gynecologic disease. A new section has been also introduced concerned with the relationship of gynecology to the sex impulse, based on the Freudian theories as to infant sexuality, with which the author appears to be in complete accord.

Part III deals exclusively with operative gynecology, and a large number of new operations are described and illustrated. The work provides a mine of information, is well gotten up, and graphically illustrated.

The Wassermann Test. By Charles F. Craig, A.M. (Hon.), M.D. (Yale); Lieutenant Colonel, Medical Corps, United States Army; Fellow of the American College of Surgeons; formerly Assistant Professor of Bacteriology and Pathology, Army Medical School, and George Washington University; Commanding Officer, Department Laboratory, Central Department, United States Army, Fort Leavenworth, Kansas. Published with authority of the Surgeon General United States Army. Illustrated with colored plates, halftone plates, and fifty-seven tables. St. Louis: C. V. Mosby Co., 1918.

Although the Wassermann test has been in use for a good many years, it is not yet thoroughly understood by the medical profession generally, and not as it should be understood by many to whom is relegated the task of working it out. In consequence it has fallen into a certain degree of disrepute, mainly because of the lack of trained serologists. In order to perform the test scientifically the entire subject must be comprehended in all its details and therefore it is essential that a fully trained serologist should do it. Dr. Craig in the work under notice made a successful attempt to dispel a great deal of the misunderstanding and confusion which exists among the members of the medical profession as to the exact value and limitations of the test, both in the diagnosis of syphilis and when used as a control of the treatment of the disease.

The book is clearly written and well illustrated and will prove of service in disseminating much needed information respecting a valuable diagnostic agent.

Society Reports.

FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Twelfth Annual Meeting, Held at Tuxedo, N. Y., October 17, 1918.

THE PRESIDENT, DR. JOSEPH B. HULETT, IN THE CHAIR.

Etiology of Pneumonia.—DR. RUFUS I. COLE spoke informally on this subject. He stated that ten years ago the study of pneumonia had been undertaken at the Hospital of The Rockefeller Institute because the mortality statistics indicated that it was the most important acute infectious disease with which the physician had to deal, and because at that time there existed very little exact knowledge concerning the nature of the infection and practically no knowledge concerning its specific therapy. Under the term pneumonia had been included all acute inflammatory diseases involving the parenchyma of the lungs. Most pathologists agreed, however, that acute lobar pneumonia was a specific acute infectious disease, and that the cause of this form of pneumonia was the pneumococcus. The lesions in the lungs due to this form of infection were characterized by the formation of an excess of fibrin. This was also seen in the lesions produced experimentally in dogs by the intratracheal injection of cultures of pneumococci. The development of the lesion was less characteristic, for in this form, as well as in bronchopneumonia, the infection seemed to spread through the bronchi. While the disease, acute lobar pneumonia, was pathologically and clinically fairly distinct, nevertheless further studies had shown that the etiologic agents in all cases were not identical, but that the pneumococci which caused the disease showed differences which permitted their separation into different classes or types. These differences were chiefly immunological, and while they were not of great practical importance as long as specific therapy was not under consideration, they became of paramount importance when attempts were undertaken to make use of immunity principle in methods of cure. Such a method was now applicable in at least one type of the disease, and for this reason attempts were being made in the Army to differentiate the different types of pneumococci occurring in the individual cases. Last winter it was reported from a number of camps that difficulties were being encountered in differentiating the types of pneumococci occurring in the cases of pneumonia. Indeed it was found difficult to isolate pneumococci from the sputum of the cases, and many of the cases showed marked peculiarities. The speaker with a group of coworkers was sent to Fort Sam Houston, Texas, to make an intensive study of the cases occurring there and to determine, if possible, the etiologic agents concerned in the different cases. This study disclosed that most of the cases of pneumonia occurring there were of the lobular type and were associated with the presence of a hemolytic streptococcus. A large number of these cases occurred as complications of, or followed, measles, but in a considerable number no association with measles could be discovered. It was then observed that this form of pneumonia was also prevailing to a considerable extent among civilians. During previous years an occasional case of pneumonia associated with *Streptococcus haemolyticus* had been seen at the Hospital of The Rockefeller Institute, but during the past winter there occurred forty-four such cases. These cases showed exactly the same features as the cases seen among soldiers. Just why the disease developed in the camps and spread from here to adult civilians was not certain. The most plausible explanation seemed to be that, owing to the crowding in the camps, direct transfer of the infectious agent from individual to individual was facilitated. with this rapid transfer a great increase in virulence of these streptococci occurred, so that they became infective not only for men whose local resistance was lowered due to the presence of measles, but also for perfectly strong, healthy soldiers. It then became quite possible for civilians coming in contact with the infected soldiers to become infected and for the disease to spread to civilian communities. The coming of spring and warmer weather limited the spread of this form of pneumonia, just as it did of other types, and as a consequence this form of disease had now practically disappeared. Very recently, however, another type of pneumonia had made its appearance. Last spring and during the summer there had been reports of the occurrence in Europe of an epidemic disease resembling the influenza which spread over the entire world in 1889-1890. From the reports which were received, the disease which had prevailed in Europe had been of a mild type and few deaths occurred. Within a few weeks the disease had suddenly appeared in this country, especially in the Army camps, but instead of being a relatively harmless infection, it was occurring here as a serious disease.

Dr. Cole stated that within a few weeks he had seen a large number of cases at Camp Devens, Ayer, Mass. The fatal character of the disease was due to the pneumonia which was present in a considerable number of cases, in practically all of the fatal ones. The speaker stated that a considerable number of cases were now being treated at the Hospital of The Rockefeller Institute, where careful bacteriological studies were being made. It was too soon to make a final report on the findings, but in most cases the influenza bacillus could be cultivated from the pharynx or from the sputum. In many cases, however, these bacilli were present in very small numbers and could be isolated only with considerable difficulty. It was recalled that in the previous epidemic during which these bacilli were first isolated, Pfeiffer reported finding them present in enormous numbers, indeed in the sputum of many cases in practically pure culture. In the lungs of the patients dying from pneumonia, influenza bacilli were frequently present, though in small numbers, but there were also present at least in most cases, large numbers of other organisms, either pneumococci, usually type III or type IV, or hemolytic streptococci, or staphylococci. The predominating form of infection seemed to differ in different places and in different camps. In one camp most of the cases of pneumonia were associated with the presence of pneumococci, in another with streptococci, and in one camp, of which the writer has knowledge, staphylococci in very large numbers were present in a third of the fatal cases. There were great difficulties in the interpretation of all these findings. In regard to the primary etiologic agent concerned in the influenza, there was room for a difference of opinion. While it seemed better, for the present at least, to consider the influenza bacillus as the primary infecting agent, there was good reason to suspect that some other organism, a virus as yet unknown, might be responsible and that the influenza bacillus was a secondary invader playing a role similar to that of the streptococcus and pneumococcus. However that might be, it seemed likely that the serious pulmonary lesions occurring in this disease were largely due to secondary infection with the streptococcus, the pneumococcus, the staphylococcus, and possibly the influenza bacillus, and that the fatal outcome in most cases at least was due to the secondary infection. Even this could not be stated with any degree of assurance, however. The fact that the pathological lesions in practically all cases had certain constant features, no matter what variety of organism was present, suggested that the secondary infection might not have so great a significance as might appear at first sight.

Dr. EDWARD C. RUSHMORE asked Dr. Cole if he found all of the pneumonias of the lobular type.

Dr. COLE replied that he did not, but that most of them were of this variety. An argument against the view that influenza bacilli were the primary etiologic agents was the fact that these organisms were also very frequently present in the pharynx of patients suffering from other infectious diseases, especially measles and whooping cough. They were also frequently present in the lungs in association with streptococci in the cases of lobular pneumonia following measles. These organisms were also found with great frequency in cases of ordinary coryza and bronchitis, especially at certain times of the year. In 1904 Lord found the influenza bacillus in the sputum of 30 per cent. of the cases of respiratory disease which he studied. In 1910 Holt isolated influenza bacilli from 40

per cent. of the children suffering from disease of the respiratory tract. In the studies made in Texas last winter, Dr. Cole said he was able to isolate influenza bacilli with much greater facility than in the cases during the present epidemic. It was possible, however, that the bacilli isolated in the present epidemic differed from those which had been found in the intra-epidemic period. But little work had, as yet, been done on differentiating different varieties of this organism. Reference was made to the work of Dr. Wollstein in which an effort was made to discover whether any differences existed between the influenza bacilli isolated from the respiratory tract and those present in cases of meningitis. No constant differences could be discovered in the organisms obtained from these two sources.

Dr. RUSHMORE stated that he had practised medicine in the same place and among the same people during the influenza epidemic of 1889 and 1890, and as he remembered, this epidemic showed the same features as that one and had affected some of the same people. He asked Dr. Cole if animals were susceptible.

Dr. COLE replied that certain strains of influenza bacilli were virulent for mice, rats, and rabbits.

Dr. RUSHMORE asked if there was no method by which to test the influenza bacilli as they did the pneumococci.

Dr. COLE said that the studies had not yet progressed so far. Dr. Wollstein had found agglutination unsatisfactory and the complement fixation test had showed no differences. This was not surprising, however, because the complement fixation method had not proven a very satisfactory method in differentiating pneumococci. Dr. Cole said he would not like to leave the impression that he believed there was another organism than the influenza bacillus concerned, though he would not be surprised to find this to be the case.

Dr. GEORGE A. LEITNER of Piermont said that the question of most importance at the present time was what to do for the patients. He would like to know whether there was anything beside a sustaining and symptomatic treatment.

Dr. COLE replied that thus far there was no specific treatment. The treatment was only symptomatic.

Dr. RUSHMORE asked what the prospects were for immunizing people against influenza.

Dr. COLE said that if the disease was due to the influenza bacillus, immunization should have some effect if we knew the proper method of producing immunity, but we could not be sure that the epidemic was due to the influenza bacillus and if it was, we were not quite certain as to the best method. The only way in which we could determine whether the production of immunity was possible was to try it in a large way as Dr. Park was doing. In regard to the immunization against the pneumococcus, for this there was a well established method that had a sound experimental basis and had been tested to some extent practically. There was very good evidence that one could immunize animals against pneumococci of types I, II, and III. Lister had reported that he had immunized a large number of miners in South Africa with excellent results. Dr. Cecil and Dr. Austin had immunized a large number of soldiers at Camp Upton and no case of pneumonia due to the type of pneumococci immunized against had occurred among those immunized, while among the men who were not immunized a considerable number contracted pneumonia. Immunization against pneumonia was being taken up in the Army to quite a large extent. The earlier vaccinations had been done with a salt solution vaccine, giving three doses as they did in vaccinating against typhoid and paratyphoid fever, but now they were using one injection of a vaccine in oil. When the oil vaccine was used, absorption went on more slowly.

Dr. HULETT stated that an occurrence that came under his observation demonstrated quite conclusively that the period of incubation for influenza was five days. Owing to certain difficulties in transportation a number of men from Camp Devens were delayed at the station at Maybrook and got off the train and mingled with the people. Some of them were coughing and spitting. Before this there was no influenza in Maybrook, but five days after these soldiers were in Maybrook people began to come down with influenza. Dr. Hulett asked Dr. Cole if he thought this epidemic was the same old grippe they had seen before, or whether it might possibly have something to do with the pneumonic plague.

Dr. COLE said he was unable to say whether this is the same form of grippe that had occurred in 1889-90, but Dr. Rushmore believed it was. The disease seen in the present epidemic was very different from pneumonic plague.

Dr. RUSHMORE said there were some cases at Camp Devens which showed skin hemorrhages and later large purpuric areas.

Dr. COLE said that he had seen cases in civil life that had nose bleed and that he had had several cases showing marked purpura. He had seen two cases with subcutaneous emphysema.

Dr. LEITNER said he had had such a case in which there was emphysema all over the back, chest and neck. The case started as one of bronchopneumonia. After the initial rise in temperature, the temperature came down; it then went up to 104°F., and the patient complained of deep-seated pain over the gluteal region. An abscess in this region was drained and a man came from the Rockefeller Institute to get a culture and left a gas bacillus serum. Study of the culture showed no specific bacillus, but the girl had crackles and a primary pneumonia. The patient recovered. He had thought the case was one of gas bacillus poisoning, though there was no history of trauma. He also referred to a case of gas bacillus infection following a mastoid operation.

Dr. COLE said that if these were gas bacillus infections, they were secondary to pneumonia.

Dr. CASTELLI asked Dr. Cole whether he had found that any of these patients with streptococcus infections got erysipelas.

Dr. COLE replied that he had seen no cases of streptococcus pneumonia complicated by erysipelas.

Address by the Secretary of the Medical Society of the State of New York.—Dr. Floyd M. Crandall made this address, in which he said that he presumed that he was to speak of the condition of the State Society. He could say that the Medical Society of the State of New York was in remarkably good condition. These war times had brought out the fact that membership in the State Society was an asset to the physician. When a man asked for a commission in the Medical Corps of the Army, one of the questions always asked was whether he was a member of the State Society. By the authorities, membership in the State Society was looked upon as a valuable fact in determining the availability of a man for service. The society had at present a larger membership than it had at this time last year. Dr. Crandall described the well-organized office of the society and commented on the accuracy and completeness with which the records were kept. He paid tribute to Dr. Wisner R. Townsend's executive ability and faithful service in having developed and systematized this part of the society's work. In speaking of the officers of the society, he stated that Dr. Halstead had gone abroad and that Dr. Lambert, who was chief surgeon of the Red Cross in France, having charge of the work from Belgium all along the line down into Italy, had taken a number of physicians with him for half time service and hoped to keep up the required supply of physicians by using college and hospital men on part time. Dr. Rooney had been assigned to service overseas and was probably on his way over at this time. Dr. McEvitt was surgeon of a large aviation corps, and had delegated his duties in connection with the State Journal to an able assistant. The attorney for the society, James Taylor Lewis, had handled during the past twelve years about 1400 cases in which suits for malpractice had been brought against members of the society. Of all these he had lost but two, and those should have been lost. These two suits have cost the society $250 damages, which was all the society had ever paid out for this purpose. In response to a request from the American Medical Association, which was asked to have committees appointed in every state for the purpose of bringing the medical profession more effectively into the service, the State Society appointed a committee consisting of the same men who were serving on the State Committee of the Council of National Defense, of which Dr. George D. Stewart was chairman. Thus far 3650 physicians from New York State had received commissions, which was consider-

ably more than the quota assigned for this State. There was never a time when there was greater harmony in the profession than at present. It was felt that lack of harmony among the members of the society in these war times would be discreditable. The Society, in numbers, in harmony, and in every way, had never been in better condition than it was today.

The Importance of the Adoption of Electrocardiography and Orthodiagraphy as Routine Measures in the Management of Disorders of the Heart.—Dr. LOUIS FAUGÈRES BISHOP read this paper. (See page 1.)

Dr. CASTELLI asked Dr. Bishop if he had any pictures showing a cardioptosis.

Dr. BISHOP said that he had no such pictures but he thought that was a name given to the long hearts sometimes found in flabby individuals.

Dr. CASTELLI asked Dr. Bishop to say something about several cardiac remedies and drugs.

Dr. BISHOP said that the electrocardiograph had taught us much about digitalis, and the Rockefeller Institute had contributed much to our knowledge of the effects of digitalis in disease. There was no doubt that a certain number of people died of pneumonia, with fibrillation of the auricle, in whom the fibrillation of the auricle might have been controlled by digitalis. These patients could not be treated with digitalis in a hurry. It was probably very good policy to have every serious case of pneumonia partially digitalized before the crisis came, in order to get control of the ventricle at that time. Digitalis was of no value as an emergency remedy. There was a time element and also a quantity element in digitalis. If one had three or four days in which partially to digitalize a patient, then in an emergency one could give massive doses, but one could not get the desired effect unless he started in time. His experience with digalen had not been very satisfactory. He preferred the whole drug. For use in his practice he had a druggist take the whole leaves and compress them into one-half grain tablets. One could not rely on the infusion unless he had a reliable druggist who made a uniform infusion. All these benign fibrillation cases that were going on from year to year were given from one to three one-half grain tablets after meals from time to time. When these people began to feel uncomfortable they would then begin to take digitalis. The main point was to get one preparation that you knew about and then to stick to that. Digitalis that did not make people vomit when it was pushed was an inert preparation, and when one met a desperate case the digitalis should be pushed until the patient vomited. It also produced catharsis. The heart patient who was once digitalized was always easier to handle.

Dr. LEITNER said he had four patients at the present time with pneumonia and a temperature of 104°F. and pulse of 100. He claimed that if one could save the difference between 100 and 130 beats of the heart every minute of every hour and every day, that meant that the heart muscle was not being worn out, and veratrum viride would do that. He had been using veratrum viride for 30 years and would continue to do so. He used Norwood's tincture and varied the dosage according to the size and type of the patient, giving three or four minims of Norwood's tincture to a large strong adult. There was nothing better than veratrum viride in puerperal eclampsia if it was used in conjunction with other remedies, chloral, etc., but one must not trifle with small doses.

Dr. CHARLES D. KLINE of Nyack said that when he was in St. Francis Hospital under Dr. Ripley they used veratrum viride for adults and aconite for children, and their results with this treatment were better than those of other men who used other drugs. Eight out of ten of their patients defervesced by crisis. He still stuck to that treatment and his results were good.

Dr. CASTELLI asked Dr. Bishop what he thought about camphor.

Dr. BISHOP said that he considered it a valuable quick stimulant. He used ampules containing 30 per cent. camphor.

Dr. HULETT asked Dr. Bishop what he thought in reference to alcohol as a stimulant in pneumonia.

Dr. BISHOP replied that he considered alcohol a poor stimulant, but if a person was accustomed to the use of alcohol he should be given his customary amount during pneumonia. He used alcohol in alcoholic patients, but not in others, except that it was useful in very sick people who presented the picture so well known in the old days as the "typhoid state."

Dr. COLE said that the question as to whether a patient had been partially digitalized was a very important one. If a patient was brought into the hospital and one did not know whether he had been given digitalis before, one ran a great risk in giving digitalis or strophanthin intravenously. Dr. Cole said that the rule in the Hospital of the Rockefeller Institute was to give digitalis by mouth to every case of pneumonia. They usually gave it for two days, using digipuratum.

Dr. S. W. S. TOMS of Nyack asked what the indications in pneumonia were for using digitalis.

Dr. COLE replied that in early uncomplicated cases they administered one-half gram of the tincture during twenty-four hours for two days. It was then discontinued. If, however, a great increase in the heart rate or irregularity developed, then they at once again began its administration. The rate and regularity of the heart were the guides as to the administration of digitalis, as it was doubtful whether digitalis had any effect on the blood pressure. There were probably one or two cases in a hundred in which digitalis was life-saving, and if by digitalizing every pneumonia case they were enabled to save these few, it was worth while. In cases in which fibrillation occurred digitalis might be life-saving. They did not give digitalis in all influenza cases, and he was not sure whether in the influenza pneumonias it was of value or not, as his experience had not been great enough. The fatal cases of grippe pneumonias that he had seen had had very marked edema and apparently had drowned in their own secretions. It was doubtful if digitalis did any good under those conditions.

Dr. LEITNER said that they were seeing patients that ran a temperature for three or four days, and one could not make out anything on one day, and perhaps on the next day they would be found with a typical pneumonia temperature, and by the next morning they would have a plain pneumonia. These were the fatal cases that ran four or five days and then flared up, and in these cases he had noticed particularly a basal pneumonia on the left side, and all of these patients seemed to have a myocardial condition. Would it be right in such a case to start digitalis and anticipate that condition?

Dr. COLE replied that he had had some experience with cases of that kind that one could not detect until late. Even in the absence of typical physical signs, one might assume that pneumonia was present.

Dr. COLE said that he had treated pneumonia cases with stimulants and without them. He had had experience in treating all pneumonia cases with strychnine and alcohol, but during the last ten years he had not used any stimulant except digitalis. He could not say that he had ever saved a patient by the use of alcohol. Morphine intelligently used was of great service.

Dr. LEITNER said that Austin Flint claimed to have cured pneumonia with quinine.

Dr. COLE said that the more he worked with pneumonia the more he realized that it was a general infection and could not be influenced by quinine or alcohol. Another point with reference to digitalis was that the standard tincture should be used. An infusion could not be standardized. In most of the camps a standard tincture was used and most drug houses were putting up a standardized tincture, so that there was no reason at present for using a tincture that was not physiologically standardized. As to the electrocardiograph, he had used it for a long time, and it had certainly changed our whole point of view of heart disease. We were no longer interested in heart murmurs, but were chiefly concerned with the functional capacity of the heart muscle.

Dr. BISHOP in closing referred to another point which he considered very important. He said that he started in the practice of medicine during the epidemic of grippe in 1889-90, when there were as many cases of grippe pneumonia in the hospitals as there were at the present time. Under the tutelage of such men as Drs. Delafield, Kinnicutt and Janeway, they treated

these cases with the so-called "trinity pill," which contained aconite, strychnine and digitalis in dosimetric amounts, giving the pill every hour. In order to determine which of these drugs produced the effect that was observed they gave 100 doses of digitalis and got no physiological effect; they then gave 100 doses of strychnine, and that produced no physiological effect. Finally they gave 100 doses of aconite, and they got a slowing down of the pulse and a fulness of the arteries, which proved that the really active element was the aconite. Under that treatment the cases ran a different course from what they were running now. They defervesced more by crisis, and if they went into collapse they were stimulated by whiskey, per rectum, and most of the patients recovered. Dr. Bishop said that when he was called to see pneumonia cases now it was too late to institute this kind of treatment, but he wished those who did see the cases early would endeavor to find out whether aconite might not prevent general edema of the lungs in pneumonia and cause the patients to have a true crisis. Aconite had a bad reputation because it had formerly been abused, but it had nevertheless a very useful place in medicine. It was a remedy of positive activity and needed skilled handling.

Surgery versus Radium in the Treatment of Carcinoma of the Bladder.—Dr. Benjamin S. Barringer presented this paper, in which he said that if he were to state briefly his opinion as to the relative value of surgery and radium in curing carcinoma of the bladder, he would say that if surgery could cure 15 cases in 100, radium could cure 20 cases. Certain peculiarities of the bladder itself and of bladder carcinomata had been responsible for the far from brilliant results of surgery. The hardest parts of the bladder to reach surgically were the bladder neck and the trigone, where eight out of ten bladder tumors were situated. Further complicating matters were the ureters emptying at the trigone and often invaded by the growth. The bladder was in constant motion, either filling with urine or being emptied, which complicated the healing after operation. These were some of the difficulties which surgery had, upon the whole, been unable to overcome. Roughly, carcinomata of the bladder presented two types, the papillary type and the flat, indurative type, the latter being a good deal more malignant than the former. Combinations of these two types were to be found. There was no other internal organ which so easily and so constantly put out a danger signal of carcinoma; this signal was hematuria. Again, there was no other internal organ which could be so readily and easily examined as the bladder. In treating bladder carcinoma radium had a distinct advantage over surgery. Under radium treatment the bladder usually did not have to be opened. The radium might be placed more or less accurately on the tumor and left there. The urine which filled the bladder acted as a screen to the normal parts of the bladder. They were steadily working toward a more accurate application of the radium. As to untoward results, the writer had had a number of radium burns. He had a general impression that the bladder from which sprang papillomata was considerably more sensitive than the carcinomatous bladder. When burns occurred they were very painful and lasted for some months. Since October, 1915, he had treated 43 cases of carcinoma of the bladder, exclusive of papillomata, at the Memorial Hospital. In the majority of the cases the diagnosis had been confirmed by microscopical examination of pieces of the tumor. In the diagnosis the cystoscopic and rectal examinations were more important than the microscopical examination. The microscopical examination, however, should be made in every instance. The fulguration of a tumor for a long period of time to determine the reaction of the tumor to fulguration was in the author's opinion a distinctly bad practice. Two of the 43 cases were early operable cases. Of the remaining 41 cases some might have been called operable, but on the whole, operation on these 41 cases would have presented but slight chance of cure. Five of the 41 cases were well, as proved by cystocopic examination for various periods up to 23 months. In two cases the tumor had recurred after being removed from the bladder by radium. Three or four more cases would probably later go into the cured column. It was on this record of five cases cured so far as the bladder was concerned for various periods of time that the writer based his claim for the efficiency of the radium treatment of carcinoma of the bladder. A detailed history of the seven cases was presented. Many of the remaining cases were dead; many came to them practically dying. The one thing radium did in these hopeless cases was to control the hematuria. In nine out of ten cases the bleeding stopped, generally for a period of some months. This was the decided benefit which followed radium treatment. Whether or not it temporarily checked the growth of the tumor was an open question.

Dr. Gerrit Blauvelt of Nyack asked Dr. Barringer to tell about the woman with carcinoma that he had treated with radium.

Dr. Barringer stated that the patient to whom Dr. Blauvelt referred was a woman who had uterine carcinoma and a metastasis became implanted around the vaginal outlet and just underneath the urethra, and manifestly the case was not suitable for operation. Several treatments were given with radium, and finally a large dose was given that apparently removed the growth. This burned the patient, but the discomfort caused by the burn was relieved by morphine. It was now two or three months since she had had treatment, and she was comparatively comfortable. The cases that did well, especially the prostatic cases, were those that were burned. In the cases that were burned one was very much more likely to get the whole growth out than in those that received milder treatment.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, November 27, 1918.

The President, Major Frank C. Hammond, in the Chair.

Medical Complications and Sequelæ of Influenza.—Dr. Thomas McCrae believed that many of the statements regarding the recent epidemic of influenza would not have been made were history more generally read. Whatever its etiology, influenza, he said, was a disease which occurred epidemically about three times in a century. Many men, naturally, did not see it more than once; some saw it twice; none, three times. Consequently, to the great majority of the profession, it came as a more or less new disease. Considering the fact of the disease being a multiple infection, the wonder was that complications occurred so rarely. Edema of the lungs was mentioned as one of the most striking of the complications of the respiratory tract. When associated with pneumonia, the usual fatal issue was the result of the pneumonia and toxemia. Dr. McCrae regarded pneumonia rather as a feature of the disease than a complication. Reference was made to the curious atypical cases of pneumonia following the epidemic of 1890. In these the pneumonic process had seemed to shift from one apex to another in a way to make the diagnosis questionable. Since a generation had now grown up which knew nothing of that phenomenon it was regarded as probable that within the next two or three years a number of cases would be diagnosed tuberculosis which were really postepidemic influenzal pneumonia. A peculiar persistence of consolidation was referred to, lasting in one case under the author's observation for nine weeks, then entirely disappearing. The presence of a slightly bloody serous effusion, small in amount which had been responsible for many of the atypical cases was mentioned as one of the particularly interesting signs in the pleura; also a curious feature had been the occurrence of fibrinous pleurisy after the recovery of the patient. Dr. McCrae was inclined to regard this as a remnant of the disease rather than as a tuberculous pleurisy. In many of the cases with well marked percussion note there had been practically no pain. The majority of cases of influenza had gone through the attack without serious heart involvement. The author had observed endocarditis only once and he had been impressed with the rarity of pericarditis. Of particular importance was the condition of the heart after the attack. Compared with the epidemic of 1890 there was, apparently, not 1 per cent. of the cardiac disturbances

following the disease. The curious cyanosis coming on early formed a striking feature of the vasomotor system. The low blood pressure was mentioned as of considerable prognostic importance. The early nosebleed in Dr. McCrae's experience was not of favorable prognostic import. Of patients with severe intestinal hemorrhage he had seen only one who recovered. The severe toxic condition in these cases was regarded as probably akin to that seen in yellow fever. In all these cases purpuric dermatitis had been extreme. Jaundice was largely of low grade, but very common if one looked for it, and in a few cases resembled the jaundice of acute yellow atrophy. Of the glands the parotid suffered particularly. In the effect on the nervous system two extremes were noted—a severe depression, and a condition of exhilaration. One patient within an hour of his death had said he never felt better in his life. It was recalled that following the disease in 1890 there was a profound depression, the effect of which in many cases lasted for a year or two. Following the last epidemic, also, there had been seen at the medical clinics many cases of bronchiectasis, and in many of these the influenza bacilli had been obtained in pure culture. This it was cautioned should be borne in mind at the present time. In Dr. McCrae's opinion there was every reason to suppose that following this epidemic there would be a great increase in tuberculosis in the next year or so. Personally he had been impressed with the number of patients who, following the influenza, had had large profuse pulmonary hemorrhage. In the majority of these cases it had been impossible to say whether the hemorrhage had resulted from a lesion of the influenza, or meant tuberculosis. There should be, therefore, particular care exercised in the examination of patients, bearing in mind the possibility of the presence of tuberculosis.

The Surgical Complications and Sequelæ of Influenza.—Dr. JOHN B. DEAVER referred to the description given by Dr. George B. Wood in the fifth edition of his Practice of Medicine of an outbreak of influenza in Rome in 1850, during which nine thousand persons were said to have died of the disease. In several recently recovered cases of influenza coming to operation for intestinal obstruction Dr. Deaver had found the intestines knotted and bound down by plastic exudate and adhesions resembling somewhat a tubercular peritonitis. While the impression was that this condition was the direct result of the influenza, positive evidence of this fact was lacking. Many of the increased number of cases of appendicitis in influenza years were regarded by Dr. Deaver as most likely socalled pseudo-appendicitis due to the gastrointestinal symptoms frequently part of the syndrome of influenza; others were undoubtedly genuine appendicitis resulting from the increased virulence of the usual intestinal microorganisms, and particularly from a predisposition on the part of the patient to appendical trouble. The explanation of lowered resistance and diathesis in Dr. Deaver's opinion served for the various neuralgias, diseases of the bones and joints, as well as for phlebitis, parotitis, and other resulting conditions requiring operation. To the surgeon the recognition of pus in the thoracic cavity was of the utmost importance. The withdrawal of seropurulent or purulent fluid by aspiration was a desirable preliminary step to thoracotomy or rib resection. A rational operation for empyema was that devised by Lilienthal, in which a wide opening in the thoracic cavity is obtained by means of a long costal incision and wide rib spreaders, the wound being closed completely, except for a wick of rubber tissue at each end of the incision. In the streptococcic pleuritis observed in epidemics of pneumonia occurring during the past year at the various training camps, late operation rather than early, as in the pleuritis following ordinary lobar pneumonia, gave the better result. Dr. Deaver believed it desirable that all pneumonia cases at the end of the second week be subjected to *x*-ray examination for early detection of the presence of fluid not evidenced by physical signs. Dr. Henry K. Pancoast was cited as stating that effusion in influenzal empyemas shows a ready tendency to become plastic and to wall off. In such cases the pleura becomes thickened and the lungs crippled by the resulting adhesions. In the total of 35 cases treated by Dr. Deaver 13 were interlobular empyemas, several of which had ruptured into the lung, and in one instance pus from the general cavity had broken through into the lung. Thoracotomy, except in rare instances, was, in Dr. Deaver's opinion, decidedly not the proper procedure in these cases. The operation of choise for empyema, he said, is rib resection, opening the pleural cavity and exploration with the gloved finger or hand, flushing and wiping the cavity with Dakin's solution and providing continuous and free drainage until the fluid is returned practically sterile. Closure of the wound is a matter of circumspection unless there is a free expansion of the lung. In Dr. Deaver's 35 cases of influenzal empyemia the mortality was 11.6 per cent.

Influenza in Parturient Women.—Dr. EDWARD P. DAVIS said that the parturient woman, for anatomical and physiological reasons, was a favorable subject for attack in the recent epidemic of influenza. In the mild attack of the disease abortion or premature labor did not occur. In the severe cases a hemolytic germ was evidently present, producing a rapidly fatal toxemia. Striking evidence of disintegration of the blood was observed in many of these cases. In early pregnancy many aborted; in those near term, labor occurred; in mid-pregnancy, interruption was rare. Among the interesting complications and sequelæ were abortion followed by persistent and often fatal hemorrhage; mammary abscess; noma or swelling of the tissue about the mouth, preceding death; pernicious nausea and vomiting, and occasional pulmonary embolism. In prophylaxis much was accomplished by keeping away from crowds and the disinfection of nose and throat with mild saline antiseptics. The firm belief that if attacked death would not inevitably ensue was of great assistance. The prompt isolation of the patient was useful in limiting the disease. So soon as a pregnant patient was attacked with nasal and bronchial catarrh, with rise of temperature, however trifling, she was put to bed; the bowels were freely emptied, a liquid diet, with abundance of water, was given, and the patient kept warm by blankets. Sweating was encouraged and the nose and throat were disinfected. With a tendency to congestion over the bases of the lungs dry cupping was very useful; applications of camphorated oil were also of value. Local foci of infection were treated as indicated; mammary abscess was thoroughly drained. The giving of acetanilid, phenacetin, salol, or aspirin was peculiarly injurious. A safe clinical rule in dealing with pregnant patients was not to interrupt the pregnancy in the presence of acute bacterial infection. That the child often escaped the disease was especially true when it was not nursed. The maternal mortality closely resembled that of puerperal septic infection. Where the streptococci did not enter the blood and were not hemolytic the mortality rate did not exceed 10 to 20 per cent.; where they did enter the blood and were hemolytic the mortality rate rose from 50 to 75 per cent. There was no positive decision that serums and vaccines gave protection or hastened recovery. Sterile horse serum was, however, of value in actively toxic cases.

Nose, Throat, and Ear Affections Complicating or Following the Recent Epidemic of So-called Influenza, with a Ventured Interpretation of Their Significance.—Dr. J. LESLIE DAVIS observed that there seemed to be a common agreement that practically every case of so-called influenza at some stage of the disease manifested symptoms of varying degree of the upper respiratory tract. The most characteristic feature of these conditions was the utter lack of any special order of invasion or degree of persistence. Reports from Army, Navy, and civilian hospitals showed the contrasts in the various structures and tissues involved, and variations in the predominating bacterial organisms. A characteristic feature was the precipitateness of invasion of the disease following the appearance of the first cases, regardless of whether or not those attacked had been in contact with the already infected. This was as true of sparsely populated districts as in a grouping of many people. Bacterial research seemed to have failed to isolate any specific organism as the exciting cause, but had found in practically all cases the usual group of bacteria common to infections of the respiratory tract, their order of predominance varying in different localities and in different individuals in the same locality. The character of atmos-

phere that seemed most frequently to predispose in normal times to infections of the upper respiratory tract was said to be that usually preceding a storm. The greater the meteorological disturbance the more common and more marked were the symptoms observed. The meteorological state seemed to favor the development of two conditions influencing the rapid spread of infection, namely, proliferation and increased virulence of the host of bacterial organisms habitually present in the nose and throat; and, second, weakening of tissue resistance to bacterial invasion. Lowered blood pressure, insufficient hepatic secretion, and toxemia were the usual accompaniments of such infections. Whether the lowered blood pressure with its effect upon the mucous membrane was the initial step in the infection or whether the circulatory disturbance and the membranous congestion in the head were both results of toxemia Dr. Davis regarded as questions for further investigation. In his experience the toxic effect of diseased faucial tonsils was a more dominant and constant factor than their infective influences, and the chief deleterious effect felt upon the liver. Considering the whole symptom complex of the disease and the fact that meteorolgical conditions over the whole earth had shown unusual disturbances during the past two or three years, the probability of such meteorological disturbances being a causative factor in the great pandemic seemed to him to be an interpretation worthy of more than passing consideration.

Dr. F. J. KALTEYER regarded as a point of considerable interest the fact that this disease apparently occurred in any climate, at any season of the year, and under almost all conditions. While many had attempted to attribute its spread to atmospheric conditions, it was often found that it spread against prevailing winds, that it would occur at the same time in the tropics and in Iceland, and that it attacked all classes of individuals. He was interested to know whether the pneumonia was due to the extension of inflammation from the throat or whether it developed in the absence of this. Pathologists whom he had consulted differed on this point. He questioned whether some of the complications were not directly attributable to the cough mechanism which perhaps influenced the drainage of the eustachian tube and led to ear complications. Personally he had been impressed with the great importance of the early treatment of cough. He called attention to the fact that in some of the cases of the so-called cardiac type the attack began as an ordinary influenza, but that in a short time there was rapid development of cardiac asthenia with death following within a few hours. We were now, he said, seeing some of the cases of myocardial weakness the result of the epidemic. Another condition of great interest and frequent occurrence was that of vomiting, with abdominal distention and occasional diarrhea dominating the whole symptom-complex. The complications were much influenced by the previous health of the patient; those with a previous nephritis or chronic valvular disease generally had their pneumonia without crisis, death occurring in the course of a few days. Unfortunately, as mentioned by Professor Davis, there was among the profession the tendency to give drugs which were depressants. These, it was stated, had a most unfavorable influence upon the disease, particularly toward the end of the fever.

Dr. D. L. DESPARD had been impressed with the comparatively few complications during the epidemic requiring operation. A possible explanation might be found in the experience at two hospitals where of 299 cases admitted 130 developed bronchial pneumonia. Of that number 91 died, or 70 per cent. None died who had no lung involvement. He had not seen any cases of appendicitis that he could definitely trace to this epidemic, although he had observed a number occurring three or four weeks following the attack of influenza. In the rib resections he had resected enough bone to allow exploration and breaking up of adhesions; he had not irrigated any more than he would in general peritonitis, or curetted to a greater degree than in the walls of an ordinary abscess cavity. Within the last two months he had operated in 12 or 14 cases of empyema; up to this time one patient had died.

Dr. RICHARD C. NORRIS claimed that in the past epidemic there had been really two epidemics—one of influenza due to its specific organism, and a widespread epidemic of bronchopneumonia frequently associated with streptococcic germs. During an epidemic, he said, one must realize that no part of the community was more susceptible to its ravages, no matter what the infecting germ, than the pregnant and parturient woman who was giving up of the precious elements of her life for the unborn member of the human family.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

DOMINION MEDICAL EXAMINATION.

Toronto, June, 1918.

ANATOMY.

1. Give (*a*) the course and relations of the right ureter in the female, and (*b*) the relations of the left kidney.
2. Describe the temporomandibular joint, giving attachment of liganents. Name the muscles connected with each movement of the mandible in mastication, and give the innervation of each muscle.
3. Describe fully the nerve and blood supply of the foot and toes.
4. Give the boundaries of the axillary space. Describe the grouping of the lymphatic nodes in the space. From what areas do they receive the drainage?
5. Describe the various steps necessary to expose the pancreas without removal of other viscera.
6. Describe fully the blood supply of the brain and of the cerebral meninges.

PHYSIOLOGY.

1. Discuss the origin of body fat.
2. Draw a diagram of a spinal reflex-arc and explain its mode of action. Give examples of reflexes and indicate their characteristic properties.
3. Enumerate the functions of the liver and discuss fully those related to carbohydrate metabolism.
4. Describe accurately the functions of the pituitary gland.
5. Describe the iris and explain its functions.
6. Discuss fully the nervous regulation of the heartbeat.

HYGIENE AND STATE MEDICINE.

1. Enumerate the ways and means by which diseases are transmitted, in order of significance.
2. Describe two methods of treatment of sewage before discharge of effluent.
3. How would you organize an educative campaign in public health and personal hygiene?
4. (*a*) How would you detect the commoner adulterations of milk? (b) What diseases may be carried or induced by milk, and how does milk become infected in such cases?
5. What is the role played by the public health nurse in a department of health?
6. What factors are accountable for the closeness of an ill-ventilated room? Discuss the general effect on the health of living in poorly ventilated quarters. Outline some tests for efficiency of ventilation in a school room.

OBSTETRICS AND GYNECOLOGY.

1. Give symptoms of carcinoma of cervix in order of their appearance. Discuss the treatment of an inoperable case.
2. Give differential diagnosis of acute appendicitis, acute salpingitis, and pyelitis. Discuss treatment of acute salpingitis.
3. Define ectopic gestation—Give early symptoms, diagnosis and treatment.
4. (*a*) Give a detailed description of fetal circulation. (*b*) The changes that take place post partum.
5. You are called to see a patient suffering from hemorrhage per vaginam during the fifth month of pregnancy: (*a*) Give possible causes; (*b*) Give a concise differential diagnosis and treatment in each case.
6. Puerperal sepsis: (*a*) Differential diagnosis between septicemia and sapremia. (*b*) Treatment of sapremia.

ANSWERS.

ANATOMY.

1. *Course and relations of the right ureter in the female:* The ureter extends from the pelvis of the kidney to the bladder. It passes obliquely downward and inward through the lumbar region of the abdomen, and downward, forward, and inward through the cavity of the pelvis to the base of the bladder, through the coats of which it passes obliquely and into which it opens by a constricted orifice. It rests upon the psoas muscle and is crossed from within outward by the ovarian vessels and the branches of the mesenteric arteries; it lies close to the outer side of the inferior vena cava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery and vein, lying behind the ileum. In the pelvis it is to the inner side of the uterine artery, and passes forward and inward below the posterior layer of the broad ligament, passing beside the neck of the uterus and upper part of the vagina and being crossed anteriorly by the uterine artery.

Relations of the left kidney: In front, fundus of stomach, tail of pancreas, splenic artery and vein, splenic flexure, descending colon; *behind,* diaphragm, quadratus lumborum, psoas, fascia covering these muscles, posterior abdominal wall corresponding to eleventh and twelfth ribs, iliohypogastric, ilioinguinal and twelfth dorsal nerves, first lumbar artery and vein, pleura; *above,* suprarenal capsule; *below,* the crest of the ilium; *externally,* spleen and descending colon.

2. The *temporomandibular joint* is a ginglymoarthrodial joint formed, *above* by the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis, and *below* by the condyle of the lower jaw. A plate of interarticular fibrocartilage lies between the bony surfaces. The ligaments are the external lateral, internal lateral, stylomandibular, and capsular. There are two synovial membranes, one above and the other below the interarticular fibrocartilage.

The *external lateral ligament* is attached above to the zygoma; below to the outer and posterior part of the neck of the mandible. The *internal lateral ligament* is attached above to the spinous process of the sphenoid bone; below to the lingula and margin of the dental foramen. The *stylomandibular ligament* is attached above to the styloid process of the temporal bone; below to the angle and posterior border of the mandible. The *capsular ligament* is attached above to the circumference of the glenoid cavity; below to the neck of the mandible.

In *mastication,* the *mouth is opened* by the action of the anterior belly of the digastric, the mylohyoid, and geniohyoid; the *mouth is closed* by the action of the masseter, internal pterygoid, and temporal; the *mandible* is *protruded* by the external pterygoids; the *mandible is retracted* by the posterior fibers of the temporal. The *grinding movements* are due to the alternate action of the two external pterygoids.

The masseter, temporal, external, and internal pterygoids are supplied by the inferior maxillary nerve; the anterior belly of the digastric and the mylohyoid, by the mylohyoid branch of the inferior dental nerve; the geniohyoid, by the hypoglossal nerve.

3. *Blood supply of the foot and toes:* The dorsal surface is supplied by the dorsalis pedis, which extends from the ankle to the first intermetatarsal space, where it divides into the dorsalis hallucis and the communicating. Branches of the dorsalis pedis are the tarsal, metatarsal, giving off three interosseous arteries. The dorsalis pedis enters the sole of the foot between the heads of the first dorsal interosseous muscle and anastomoses with the deep branch of the external plantar artery (thus completing the plantar arch). The plantar surface is supplied by the internal and external plantar arteries. The internal is the smaller of the two and ends on the inner side of the great toe, and gives branches to join the digital arteries of the three and a half inner toes. The external is larger and supplies four digital branches to three and a half outer toes, joining the dorsal artery of the foot in the first interosseous space. The anterior and posterior perforating arteries are connected by the dorsal interosseous arteries on the dorsum of the foot; and in the sole, the posterior joins the plantar arch and the anterior joins the plantar digital arteries.

Nerve supply of the foot and toes: Branches of the internal and external plantar; the internal supplies cutaneous branches to the sole of the foot, muscular branches to abductor hallucis and flexor brevis digitorum, and four digital branches—the first supplies inner border of first toe and the flexor brevis hallucis, the second supplies the adjacent sides of the first and second toes and the first lumbricalis, the third supplies the adjacent sides of the second and third toes, and the fourth supplies the adjacent sides of the third and fourth toes and joins a branch from the external plantar.

The external plantar passes across to the outer side of the foot with the external plantar artery, supplying on its way the abductor minimi digiti and accessorius; at the outer border of the latter muscle it divides into two branches:

Superficial.—Which divides into two digital nerves, one supplying the outer side of the little toe, the flexor brevis minimi digiti, and the two interossei of the fourth space; the other supplies the adjacent sides of the fourth and fifth toes and communicates with the internal plantar.

Deep or muscular.—Accompanies deep part of external plantar artery, supplying the adductor obliquus hallucis, adductor transversus hallucis, three outer lumbricales and interossei of inner three spaces.

The dorsal surface is supplied by the musculocutaneous nerve, which supplies all the toes except the outer side of little toe, which is supplied by small saphenous nerve. The *internal* branch of the musculocutaneous passes over ankle to inner side of first toe and adjacent sides of second and third toes, *communicates* with internal saphenous and anterior tibial nerves. *External* supplies adjoining sides of third, fourth, and fifth toes; *communicates* with short saphenous.—(From *Aids to Anatomy.*)

4. The axillary space is *bounded: Anteriorly,* by the clavicle, subclavius, pectoralis major, costocoracoid membrane, pectoralis minor; *posteriorly,* by the subscapularis, teres major, and latissimus dorsi; *internally,* by the first four ribs, first three intercostal muscles, serratus magnus; *externally,* by the humerus, coracobrachialis, and biceps.

"The *axillary lymphatic glands* are generally twelve or more in number, but both their number and size are very variable. They may be roughly classified into three groups, as follows: The *axillary glands,* from four to six in number, are placed along the axillary vessels in the outer wall of the axilla. They receive the lymphatics vessels which ascend from the limb, and are consequently most prone to enlargement in such surgical conditions as poisoned wounds of the fingers and other inflammatory affections of the limb. The *pectoral glands,* four or five in number, lie farther forward on the serratus magnus muscle, near the long thoracic artery, at the lower border of the pectoral muscles—that is, in the anterior wall of the axilla. These glands receive the lymphatics from the mamma and front of the chest, and are consequently the first glands to be enlarged in such diseases of the mamma as scirrhus, and after blistering and other superficial inflammations of the chest and upper part of the abdomen. The *subscapular glands,* three or four in number, are situated at the back of the axilla, along the subscapular vessels, and therefore in the posterior wall of the axilla. This group of vessels receives the lymphatic glands from the back and is therefore most liable to enlargement after bedsores."—(From Berry's *Regional Anatomy.*)

5. The pancreas may be exposed for dissection in three different ways: (1) By raising the liver, drawing down the stomach, and tearing through the gastrohepatic omentum and the ascending layer of the transverse mesocolon. (2) By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse mesocolon and raising its ascending layer. (3) By dividing the two layers of peritoneum, which descend from the great curvature of the stomach to form the great omentum; turning the stomach upward, and then cutting through the ascending layer of the transverse mesocolon.—(From Gray's *Anatomy.*)

6. *The blood supply of the brain and cerebral*

meninges: The *blood supply of the dura* comes from the anterior, middle, and posterior meningeal arteries. These all come, except the small anterior meningeal branches and a small posterior branch, from the external carotid. The blood passes into the diploic veins, and from there passes chiefly into the lower occipital and lateral sinuses. Some of it, however, returns in the venæ comites. It all returns down toward the base of the skull. The most important of the arteries is the middle meningeal, both on account of its size and its distribution above important functional areas.

The *blood supply to the pia mater and brain substance* comes from the internal carotid and the vertebral arteries. The branches of the former artery give off the anterior and middle cerebral, the posterior communicating and anterior choroid. The vertebral arteries give off the inferior cerebellar, while the basilar branch of the vertebrals gives off the transverse, anterior cerebellar, superior cerebellar, and posterior cerebral arteries.

The anterior, middle, and posterior cerebral arteries are the three largest and most important. By their anastomoses the circle of Willis is formed. From the circle of Willis and the beginnings of the three arteries mentioned several groups of vessels, six in all, are given off. They enter the base of the brain and supply the great basal ganglia and the adjacent white matter. They are called the *central arteries*, they do not anastomose, and they are the vessels usually affected in cerebral hemorrhages of adult life. One set of these central arteries, the *internal striate*, passes up and supplies the two inner segments of the lenticular nucleus, the caudate nucleus, and anterior part of the internal capsule. Another set, the *external striate*, divide into anterior or lenticulo-striate branches which supply the lenticular nucleus and posterior part of the caudate. The *cortical arteries* are the terminal branches of the great cerebral arteries. They anastomose with each other but slightly. They are distributed very widely and carry much more blood than the central groups. The cortical arteries are distributed in the pia, and from there they pass in two sets, a superficial and a deep, into the gray matter, and for a short distance into the white matter. They pass straight in at right angles to the surface. They have richly arborescent branches which do not anastomose.

The *veins of the cerebrum* are: 1, the superficial cerebral; 2, the deep cerebral veins; 3, the cerebral sinuses. 1. The superficial cerebral veins are venæ comites. Those on the convex and mesial surfaces empty chiefly into the superior longitudinal sinus, as described; those on the basal surface and temporal lobes empty into the cevernous and lateral sinuses. These veins have no valves, and their walls are very thin and without muscular fibers. 2. The deep cerebral veins, or venæ Galeni, receive the blood from the lateral ventricles and from some of the central arteries supplying the basal ganglia. They empty into the straight sinus. These deep or central veins when compressed lead to stasis and internal hydrocephalus. 3. The *cerebral sinuses* are fifteen in number. The important ones are the superior and inferior longitudinal, the straight, the lateral, the occipital, the cavernous, and the superior and inferior petrosal. They carry blood for the most part in a direction from before backward, and convey it eventually to the internal jugular.

Most of the blood of the convexity and mesial surface must pass into the longitudinal sinus, but there is a slight connection of some of the veins with the superior petrosal and straight sinuses. The superior longitudinal sinus also communicates slightly with veins of the scalp and with the facial vein. Some of the blood from the mesial surface also goes to the veins of Galen. —(From Dana's *Diseases of the Nervous System.*)

PHYSIOLOGY.

1. *Origin of body fat:* "The modern point of view is that the fat of the body originates partly from the fat of the food, particularly in carnivora, and partly from the carbohydrate of the food, especially in herbivora, in whose diet this foodstuff forms such a large part. The possibility that fat may also be formed from protein food must be accepted in accordance with what has been described concerning the intermediary metabolism of the protein. So far as the amino-acids formed from the food protein during digestion are not reconstructed into the body-protein of the animal, they are deamidized, and the organic acid grouping left may be converted to sugar and glycogen, hence probably also to fat. Protein constitutes relatively only a small fraction of the daily diet, and the modern point of view is that body fat is formed in the first instance from food fat and food carbohydrates."—(Howell's *Physiology.*)

2. *Reflex actions* are involuntary or unconscious movements due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve. *Example:* The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendor, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

Illustrations of morbid reflex action can be seen in tetanus, when a slight touch, or even a breath of air, on the skin may cause convulsions of the whole body; also in the vomiting of pregnancy.

3. *Functions of the liver* are: The formation of bile, urea, uric acid, creatinine, and antithrombin; the production of heat; the conversion of hemoglobin into bile pigment, and the glycogenic function (formation and storage of glycogen).

"The facts connected with the formation of glycogen, as well as with its transformation as at present generally accepted, may be stated as follows: The dextrose or glucose into which the carbohydrates are mainly converted by the action of the digestive fluids is absorbed into the blood of the portal vein and carried direct to the liver, where a certain portion of it diffuses across the capillary walls into the surrounding lymph-spaces; by the action of the cells or by a special enzyme it is then dehydrated and temporarily deposited under the form of the non-diffusible body glycogen. At a subsequent period, and in proportion to the needs of the system, the liver cells, through the agency of a ferment, transform the glycogen into glucose or dextrose by the addition of a molecule of water, after which it is returned to the blood, by which it is transported to the systemic capillaries, where it disappears again, diffusing across the walls of the capillaries into the surrounding lymph-spaces to play a part in the general nutritive process. Though the final disposition of the sugar is uncertain, it is highly probable that after its delivery to the muscles, for example, it may be directly oxidized or temporarily stored as glycogen or possibly be used in the formation of living material. Ultimately, however, through oxidation (glycolysis) it yields heat and contributes to the production of muscle energy. Should there be a failure on the part of the liver cells to store up the usual percentage of the absorbed sugar, by reason of impaired nutrition, disturbance of the portal circulation, or a larger excess of sugar in the blood of the portal vein, it would pass through the liver into the blood of the general circulation and increase the percentage amount of sugar above the normal (0.1 to 0.2 per cent.), establishing the condition of hyperglycemia. This would soon be followed by its elimination from the blood by the kidneys and its appearance in the urine, giving rise to a glycosuria."—(Brubaker's *Textbook of Physiology.*)

4. *Function of the pituitary gland:* "The *anterior* lobe is concerned with the process of growth, hypertrophy leading to overgrowth of the skeleton, and partial removal to failure of development of the body as a whole and of the sexual glands. Extracts of the *posterior* lobe, when injected into an animal, have a direct action on plain muscle all over the body; they cause constriction of the arterioles and a rise of blood pressure, contraction of the muscular coats of the digestive tract and of the bronchioles, and contraction of the uterus. The extracts also produce an increased flow of urine, which was at first attributed to the presence of a substance

having a specific effect upon the renal cells; it is probable, however, that the diuretic effect is merely an indirect result of the more rapid flow of blood through the kidney which follows the injection of the extract. Extracts of the posterior lobe increase the secretion of milk, and after the injection a larger amount of milk is formed by the animal in the course of twenty-four hours."—(Bainbridge and Menzies' *Essentials of Physiology.*)

5. "The *iris* is a colored membrane, circular in form, hanging behind the cornea immediately in front of the lens, and perforated in its center by an aperture of variable size, the *pupil;* it serves to regulate the amount of light admitted to the interior of the eye, and cuts off the marginal rays which would interfere with the sharpness of the retinal image. Its peripheral border springs from the head of the ciliary body and the ligamentum pectinatum. Its free inner edge, the boundary of the pupil, lies upon the anterior capsule of the lens when the pupil is contracted or moderately dilated; with maximum dilatation of the pupil it hangs free in the anterior chamber. The iris separates the *anterior* from the *posterior chamber* of the eyeball. Its anterior surface presents great variation in *color* in different eyes, and is marked by radially directed, wavy lines, converging toward the circle of irregular elevations and small depressions (crypts) situated near the pupil; other finer lines are seen extending from this ring to the pupil. This appearance is produced by the subjacent blood-vessels."—(May's *Diseases of the Eye.*)

The *functions of the iris* are: (1) To regulate the amount of light which reaches the retina (in intense light the pupil becomes smaller); (2) to lessen spherical aberration by cutting off peripheral rays of light.

6. The nervous mechanism consists of an inhibitory and an accelerator supply. In addition, there are various intrinsic ganglia in the heart which are supposed to be responsible for the heart-beat. The *cardio-inhibitory* center is connected with the nucleus of the vagus in the floor of the fourth ventricle, and the fibers from it pass to the heart along the vagus nerve. Its function is to slow the beat of the heart. It is sometimes known as the anabolic center, because it lessens the rate and force of the heart and so allows time for building-up processes (anabolism). If the peripheral end of the cut vagus is stimulated, the heart is slowed and may be entirely stopped. It is a tonically active center, that is, it acts continuously, so that the simple cutting of the vagus takes off the brake and lets the heart run away.

The *cardio-aecelerator* center is also in the floor of the fourth ventricle. It acts through the sympathetic fibers which descend in the spinal cord and leave it through the anterior roots of the first and second dorsal nerves, and go thence to the cardiac plexus. This center keeps up the rate of the heart beat.

These centers may be stimulated by afferent impulses, such as *psychic* from the cortex cerebri, or *cutaneous*, or *visceral*. The centers are also affected by the state of the blood; thus excess of carbon dioxide in the blood, as in the beginning of asphyxia, stimulates the cardiac centers and makes the heart beat more strongly and more rapidly. Increased temperature of the blood also increases the rapidity of the heart's action.

HYGIENE AND STATE MEDICINE.

1. *Diseases are transmitted:* By personal contact (as in case of syphilis); by animals suffering from the disease (as anthrax); by animals, such as flies, acting as carriers (as trypanosomiasis); by animals, such as mosquitoes, acting as intermediary hosts (as malaria); by the air (as diphtheria); by the dust (as influenza); by droplets of saliva (as tuberculosis); by water (as cholera); by food and milk (as typhoid); by human carriers (as typhoid).

The *order of significance* depends upon the disease under discussion.

2. *Two methods of treatment of sewage before discharge of effluent:* (1) The biological (or bacterial) process of sewage disposal; (2) the septic tank process.

(1) The biological (or bacterial) process:

"The actual changes which take place in sewage, as the result of bacterial action, are somewhat complex and obscure, but they have been aptly described by Rideal as consisting mainly of three stages. In the first stage, or that of anaërobic liquefaction and preparation by hydrolysis, the albuminous matters, cellulose, and fats are broken up into soluble nitrogenous compounds, fatty acids, phenol derivatives, gases, and ammonia. In the second stage, or that of semi-anaërobic disintegration of the intermediate dissolved bodies, a further formation of ammonia, nitrites, and gases takes place. In the third stage, or that of aeration and nitrification, ammonia and carbon residues are changed into water, carbon dioxide, and nitrites.

"A *septic tank* is a specially constructed tank for the treatment of sewage; in it the sewage as such is destroyed, and new substances are built up in its place. In *Cameron's septic tank* system 'the sewage is first led into a tank from which air and light are excluded. Digestive changes take place in the sewage within this tank as the result of anaërobic bacterial action, which is favored by the darkness, the absence of air, and the perfect stillness at which the sewage is maintained. Under these circumstances much of the solid matter is rendered soluble and dissolved.' "—(Notter and Firth's *Hygiene.*)

3. An *educative campaign* should be begun by interesting the leading men in the community, physicians, scientists, teachers, clergy; get them enthusiastic, and then present the facts to the pupils in the schools; insert propaganda in the newspapers and magazines, and try and get the editors interested; cooperate with all local and general organizations which bear on health work, also with organized charities and dispensaries, as well as civic clubs and social service centers; instruction is more necessary than legislation; get the "home" and the "school" interested; inaugurate lectures, and use charts, illustrations, lantern slides, movies; distribute leaflets, bulletins, and other printed matter; get up exhibitions, shows, etc. (these must be carefully planned, and all possible cooperation must be secured; care will be needed in selecting the committee, location, hall, program, exhibits).

4. To Detect the Commoner Adulterations of Milk.—The specific gravity of the milk should be observed; milk which has been skimmed will show an increased specific gravity; milk which has been watered will show a decreased gravity; with this test there should be made a comparison with normal milk in regard to color, opacity, and density. *Test for formaldehyde in milk:* "Commercial sulphuric acid to which has been added five drops of tincture of the chloride of iron to the ounce is the reagent. A half inch layer of this is put into a test tube and the milk flowed on top. After a few minutes a violet color develops in the milk in the presence of formaldehyde." "Milk containing *borie acid* or *borates* colors turmeric paper brown." "The presence of *foreign coloring matter* in milk is easily shown by shaking 10 c.c. of the milk with an equal quantity of ether; on standing, a clear ether solution will rise to the surface; if artificial coloring matter has been added to the milk the solution will be yellow colored, the intensity of the color indicating the quantity added; natural fresh milk will give a colorless ether solution."—(From Gardner and Simond's *Practical Sanitation.*)

Diseases specially liable to be conveyed by the ingestion of milk: Tuberculosis, typhoid fever, scarlet fever, diphtheria, tonsillitis, cholera, and gastrointestinal disorders.

The milk may come from a diseased cow; it may become contaminated by the milker, the container, the surroundings, the water used to wash the cans or to adulterate the milk; or it may become contaminated at the dealer's or purchaser's house by being left uncovered, exposed to flies, etc., or by not being kept in a cool place. The only way to prevent the transmission of disease by milk is to insist on a thorough inspection of all dairies and sources of milk supply, and to educate the public in the care of milk between the time of its purchase and its consumption. The inspection should include: the color, reaction, specific gravity, sediment, taste, odor, acidity, total quantity of solids and of water; the percentage of cream, fats, lactose, casein, and ash; the presence or absence of preservatives, coloring matter, added solids, dilution, pathogenic microorganism, dirt, or other foreign matter. There

should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transporting the milk.

5. The *public health nurse* is of the utmost importance; she aids the health authorities, physicians, families in sickness, and the community at large; she aims more at the prevention of disease and distress than the cure of it, though the latter is very carefully attended to as well; she aids in schools, visitation of sick, control of special diseases such as tuberculosis, and the general sanitary instruction of households; she aids the needy in getting in touch with the proper charity organizations; she reports births and sickness to the health authorities, and by her advice and instruction prevents the spread of infectious diseases; she explains the necessity for calling in a physician and often sees that his instructions are carried out; she acts as hygienic adviser in many households, and is particularly useful in aiding young mothers. The public health nurse, if experienced and tactful, has unlimited possibilities for good.

6. *The closeness of an ill-ventilated room* is due to the following factors: Increased amount of carbon dioxide, diminished oxygen, odors and emanations from the bodies of persons in the room, increased temperature of the room, the saturation of the air with vapor, the presence of "crowd poison" or "fatigue toxins."

The *dangers of impure air* are: Drowsiness, headache, digestive disturbances, mental dullness, and disease or liability to take disease. The chief danger to health is in the increase of carbon dioxide, the presence of crowd-poison, dust, irrespirable gases, and bacteria.

Pettenkofer's method of determining the percentage of carbon dioxide in the air: A large cylindrical container of known capacity, say, 15 liters, is filled with the air to be examined; a known volume of barium hydroxide is then added and shaken up with the air. The carbon dioxide combines with the barium hydroxide to form a barium carbonate, which is insoluble, and also incapable of acting upon an indicator. The barium hydroxide employed is of known strength, *e g.*, it may be of such strength that 1 c.c. of the solution neutralizes 1 c.c. of carbon dioxide at normal temperature and pressure. If then we find that 10 c.c. of the barium hydroxide has been neutralized by the carbon dioxide present in the air, we know that 10 c.c. of carbon dioxide is present in 15 liters or 15,000 c.c. of the air examined.

The *relative humidity* may be obtained by the use of hygrometers and psychrometers.

OBSTETRICS AND GYNECOLOGY.

1. *Carcinoma of the cervix:* The symptoms are hemorrhage (which gradually becomes more constant and profuse), pain, and discharge (this is at first serous and odorless, later becoming bloody, mucopurulent, and of a fetid odor). The diagnosis is made on the physical and microscopical examination. The cervix is hard and nodular, and the mucous membrane seems immovably fixed to the underlying tissue. These nodules break down, the entire cervix becomes ulcerated, or large cauliflower-like masses may fill the upper part of the vagina. The diseased tissue is friable and bleeds upon touch.

Treatment for inoperable carcinoma of cervix: Careful nursing, scrupulous cleanliness with douches containing potassium permanganate or bichloride of mercury; morphine for the pain; the dead tissue may be removed by scissors or curette; tonics and nourishing food are indicated.

2.

APPENDICITIS.	SALPINGITIS.
1. No previous local disturbances.	1. Genitourinary functions previously disturbed. Usually a history of gonorrheal or puerperal infection.
2. Chill usually absent.	2. Chill may precede fever.
3. Pain in right iliac region, sudden onset, acute, and not radiating to thighs.	3. Gradual onset, pain dull, continuous, and radiating.
4. Fever of variable degree.	4. Fever often entirely absent.
5. Muscular rigidity on right side of the abdomen.	5. No muscular rigidity unless complicated by peritonitis.
6. Inflammatory exudate about appendix three to five days after onset of symptoms.	6. Inflammatory exudate in the pelvis felt by vaginal examination at the onset of the symptoms.
7. Vaginal examination is rarely painful in appendicitis.	7. Always painful in tuboovarian disease.

—(Findley.)

In *pyelitis*, there are usually pain and tenderness over the kidney, fever, frequency of urination, the kidney may be enlarged and palpable, the urine contains pus, albumin, bacteria, and epithelial cells, the urine is acid unless cystitis is also present. The cystoscope and catheterization of the ureters may aid in diagnosis.

Treatment of acute salpingitis consists in rest in bed, free purgation with Rochelle salts (℥1 every hour), hot vaginal douches, and hot applications to the abdomen. Liquid diet is indicated, and if the pain is severe morphine may be necessary. If the symptoms become more severe celiotomy is indicated.

3. *Ectopic gestation* is a pregnancy in which the ovum is developed outside of the uterine cavity. The *Symptoms* for the first few weeks are exactly similar to those of normal pregnancy. Later, sharp, cramplike, periodic pain occurs and is reflected down one thigh. About the third month menstruation returns. The bleeding is profuse and attended by some pain Flesh-like masses (decidua) are discharged. Nearly all the signs of normal pregnancy are present. Physical examination will reveal a softened cervix, an enlarged and displaced uterus, and the presence of a small cystic tumor, sensitive and adherent, on one side of the uterus. *Rupture* is attended by great pain and syncope. If the hemorrhage is intraperitoneal and extensive, death results in a few hours, attended by symptoms of profound shock; rapid, weak pulse; blanched cold skin; sighing respiration, and fall of temperature. If the hemorrhage is extraperitoneal, it will be limited and the symptoms of shock and bleeding will be slight. Before rupture the diagnosis is difficult, but afterward the history of early pregnancy, intense pain, syncope, and collapse will distinguish this condition.

The *treatment* consists of removal of the affected tube and ovary as soon as the diagnosis is made. In late extrauterine pregnancies it may be necessary, after controlling hemorrhage, to suture the sac-wall to the lower angle of the abdominal incision.—(*Pocket Cyclopedia*)

4. *The fetal circulation:* "The arterial blood coming from the placenta to the fetus travels along the umbilical vein to the liver. After giving off several branches to the left lobe it divides into two streams, the larger joining the portal vein and thus entering the liver, the smaller passing directly into the inferior vena cava through the *ductus venosus*. In the inferior vena cava the blood carried by the hepatic veins and ductus venosus mixes with the blood which has circulated through the lower extremities. On entering the right auricle the blood of the inferior vena cava is directed by the Eustachian valve, through the foramen ovale into the left auricle, and from thence into the left ventricle. The left ventricle forces it into the aorta, and it is then distributed to the head and upper extremities, a small quantity only passing into the descending aorta. The blood which has circulated through the head and upper extremities returns to the heart along the superior vena cava, the blood then passing into the right ventricle and pulmonary artery. A small part of the blood in the pulmonary artery is con-

veyed to the lungs, but the major part passes through the ductus arteriosus into the aorta at the commencement of the descending portion. This blood is distributed to the lower extremities, a certain portion of it entering the hypogastric arteries and being conveyed to the placenta."—(Ashby's *Physiology.*)

Changes that occur in the fetal circulation at birth: The hypogastric arteries dwindle and close, the foramen ovale becomes obliterated, the ductus arteriosus and ductus venosus become obliterated, the umbilical vein becomes impervious, and the Eustachian valve atrophies.

5. The possible causes of hemorrhage per vaginam, during the fifth month of pregnancy, are: Placenta prævia, threatened or inevitable abortion, and ectopic pregnancy. *In placenta prævia* the hemorrhage is sudden, and may be accompanied by vertigo, restlessness, syncope, feeble pulse. The placenta can usually be felt by the examining finger in the cervical canal. In *threatened abortion* there are pain dilated os, and possible protrusion of the ovum, besides the hemorrhage; the pains are like miniature labor pains. In *incomplete abortion* the ovum is expelled, but the membranes remain behind.

For symptoms of *ectopic gestation* see Question 3.

Treatment of placenta prævia: (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation turn the child and make the breech engage in the os; or, if the head presents forceps may be used if speedy delivery is necessary. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child.

"*Treatment of threatened abortion* includes rest in bed with absolute quiet; the administration of nerve sedatives, preferably suppositories of opium, one grain of the aqueous extract morning and evening; this may be supplemented by teaspoonful doses of the fluid extract of viburnum prunifolium four times daily. If the abortion is due to general disease, such as typhoid fever, pneumonia, phthisis, or valvular heart disease, no attempt should be made to prevent it."—(Gould and Pyle's *Pocket Cyclopedia.*)

Management of inevitable abortion: "Two methods of treatment have been advised for these cases. The first is *the expectant plan:* Place the patient in bed, and if the bleeding is profuse insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses (5½) of the fluid extract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary, when the uterus refuses to contract and hemorrhage persists after the use of the curette."—(Gould and Pyle's *Pocket Cyclopedia.*)

For *treatment of ectopic gestation* see Question 3.

6. In *septicemia,* the signs and symptoms are more pronounced (than in *sapremia*), and in addition the rigors are more severe, the temperature persistently higher, the pulse more rapid, the lochia are frequently less fetid, there is abdominal pain, the patient looks and feels ill, the eyes are sunken, sometimes delirium may occur, the tongue becomes dry and glazed, vomiting may occur, and an offensive diarrhea may be present; sometimes a skin eruption is noticed.

"*The treatment of puerperal sepsis* is both local and general. Locally a thorough disinfection of the whole genital canal is called for in every case. It may appear unnecessary, and may prove, on actual experience, to be even harmful, but no one can tell beforehand how necessary this procedure is. In the vast majority of cases it is productive of the greatest good. It is only occasionally useless, and very rarely actually harmful. It should precede all other treatment for puerperal infection. The method of disinfecting the genital canal may be described as follows: A double tenaculum, a large, dull curette, a placental forceps, and an intrauterine catheter are boiled for fifteen minutes. The operator disinfects his hands and arms and wears sterile gloves. The patient is placed in the dorsal posture across the bed, with her buttocks resting on a rubber pad. The external genitalia and the vagina are scrubbed with tincture of green soap and pledgets of cotton; the vagina is douched with a sublimate solution, 1:2000. The operator then seizes the anterior lip of the cervix with a tenaculum. An intrauterine douche of sterile water, at least a quart, is administered. Then, with the placental forceps, and, if necessary, with a dull curette, the uterine walls are gone over thoroughly but lightly in all directions, six to twelve times, until nothing is brought away but bright blood. A second intrauterine douche concludes the treatment. If the womb is flabby and large, with a tendency to flexion, so that the drainage of the uterine cavity is not good, it is advisable to pack it with iodoform or sterile gauze. In addition to cleansing the uterine cavity, false membranes or areas of inflammation and localized infection on the cervix or vagina should be treated by the application of a solution of nitrate of silver, a dram to the ounce. It may be necessary to repeat the intrauterine douches several times—in fact, several times a day for many days; in this case plain sterile water only should be used. The general treatment is stimulating. The patient should have as much food of an easily digestible character, chiefly milk, as she can assimilate, and as much alcohol as she can consume without showing the physiological effects of it. Digitalis is useful as long as the pulse is above 110. Strychnine may be combined with it in suitable cases. To tide the patient over emergencies, carbonate of ammonium in large doses, by the bowel, and nitroglycerin, hypodermatically, may be required. Inhalations of oxygen may be of service. Absolute rest and freedom from all disturbances, mental and physical, must be insisted upon, and the patient should be given the best nursing that the family can afford."—(*Hirst's Obstetrics.*)

(*To be concluded.*)

Codliver Oil in Leprosy.—Balzer reports the case of a scrofulo-tuberculous leper who had failed to benefit by chaulmoozra oil and eucalyptus. Having passed through a severe pneumonia the surface manifestations of leprosy showed improvement while the scrofulo-tuberculous lesions dominated the picture. Codliver oil was now pushed and all symptoms improved notably save albuminuria. At present both disease processes seem quiescent. The rationale of this improvement is obscure. The two types of bacillus, as is known, have a strong resemblance, and codliver oil may act through some property shared by both.—*La Presse Médicale.*

Health of Holland.—The death rate in this country has remained constant during the war. Despite this fact there were many cases of contagious disease in the first four months of the present year. For example, there were 4,773 cases of diphtheria as compared with 2,095 for the same period last year. There were also 1,273 cases of typhoid as against 324 for 1917. These two maladies are still prevalent. The total death rate, however, was even less for certain months than in 1917. —*Nederlandsch Tijdschrift voor Geneeskunde.*

TYPHUS FEVER.

BY H. T. M. K. RAHMET BEY, M.D.,

CAIRO, EGYPT.

THE word typhus is of Greek derivation, meaning smoke or vapor. Typhus has been the curse of the pauper; it pertinaciously haunts the poverty stricken huts; uncleanliness is its abode of choice; filth is the pabulum that lends to its ferocity.

History.—The disease is probably as old as mankind; Hippocrates applied the word, stupor, to the mental phenomenon of a disease that probably was nothing but typhus. The black death that devastated Asia, Europe, and Africa was very likely a pandemic of the disease; it started from a focus in the Crimea; spreading thence, it carried in its wake panic and confusion that did away with all the barriers of morality, decency, and humanity; it is believed that it swept away one fourth of the earth's population; in Europe it appeared in 1348. In time the disease abated through exhaustion; but ever and anon the dormant embers would blaze afresh to work havoc. Its autonomy was first recognized in 1810; it did not, however, become a distinct disease till 1829, when Gerhard demonstrated its separate entity.

Typhus usually trails armies; in war times it has been the bane of the contending forces because of the unhygienic conditions prevailing. The disease that decimated Napoleon's troops in the Russian campaign was very likely typhus; in 1813 it was spread and scattered throughout western Europe by the forces of both parties; the Russians alone lost about 62,000; of the 30,000 French prisoners, nearly 90 per cent. died from it; the Jews of Vilna and the vicinity lost about 60,000; Danzig lost 8,000; the French lost altogether about 80,000; it continued its ravages in 1814; Prussia alone lost about 200,000 in the two years. Since then, it has convulsively continued through the different parts of the world. The Russo-Japanese war experienced it; a severe recrudescence appeared in the last Balkan war; the present terrific conflagration has tasted its bitter pills.

Etiology.—The microbic nature of the disease was suspected in the latter part of the last century when it was supposed that the virus circulated in the blood. About 1881 Klebs described a bacillus and Mott a micrococcus-like body, as the cause of the disease. Calmet claimed in 1892 to have found a flagellated body as the agent causing it. In 1893 Bruhl ascribed the disease to a diplococcus. Gottschlich in 1903 attributed it to a babesia; in the same year Krunpecker described inclusion-bodies as being probably associated with the specific etiology of the disease. Since then many views and theories have been advanced. Ricketts in 1909 described a bacillus which clearly resembles that described later by Plotz. Proescher attributed the disease to a diplococcus which is liable to appear as a diplobacillus. Plotz described his pleomorphic bacillus in the *Journal of the American Medical Association* in 1914; Baehr, Olitsky, and Plotz describe the bacillus as a small gram-positive organism which grows under anaerobic conditions. Arnheim isolated a bacillus from the blood, sputum, and urine of typhus cases. Furth in China found that the saprophytic *Bacillus fecalis alkaligines* acted as the exciting cause of typhus. The latest views, however, are that the Proteus (X 19) is the causative agent of typhus or at least the agent most intimately connected therewith, together with the other proteus organisms. Braun and Solomon maintain that the proteiform organisms of typhus are not always identical with each other, and that they greatly vary in their agglutination properties when inoculated in animals; according to them, several types of races of the proteus can be made out; during typhus the Proteus (X 2) may be transformed to the Proteus (X 19). The different proteus organisms are very likely only modifications of the same.

In 1909 Comte, Counseil, and Nicolle discovered that the body louse was the agent responsible for the transmission of typhus. Nocht, Halberkann, and Curschmann, however, contend that the body louse is not the sole agent in the transmission of the disease. Their assertion is practically correct; but it does not invalidate the fact that the body louse is the principal agent in the transmission.

The louse which belongs to the genus Pediculus, the sub-order Parasita, the order Hemiptera, and the class Insecta, is flat, elongated, and wingless, possessing a head, a thorax, and an abdomen. The head is small and has a short, strong proboscis which contains a stylet; one part of the stylet is adapted for piercing the skin, another for injecting an irritating secretion to induce hyperemia, and a third for sucking the blood from the congested surface. Each louse has three pairs of short, stout legs attached to the thorax; these legs end in strong claws. The female is larger than the male and lays about 20 eggs at a time. Some maintain that it takes the nits from 6 to 15 days to hatch; others say from 2 to 4 weeks. Wulker gives the following as the stages in the nits' development: (1) The freshly laid eggs are full of yolk granules; (2) the differentiation of the yolk into uniform germinal spheres soon takes place; (3) the larva's body is at length outlined (4) this is followed by the anlage of the head, the body, and extremities; (5) the

larva is now completely developed; (6) the hatched and empty egg is left behind. These stages are completed in from 4 to 6 days at room temperature.

Several crops of eggs are laid every year. The nits are small, white, and ovoid in shape; one side is cut, being nature's provision for the process of hatching. The young resemble the adult in every respect, except they are paler in color; they generally molt four times before maturing, feeding between each molt.

Lice usually move sidewise; they do not travel far but remain closely attached to the host. One is infected with lice either from contact or from wearing clothes harboring the parasites. Lice starve in a few days if deprived of their food. There are three varieties of lice, viz., *Pediculus capitus*, or the head louse; *Pediculus pubis*, or the crab louse; and *Pediculus vestimenti* or the body louse. The head louse inhabits the scalp and lays its nits on the hair to which they tenaciously stick. The crab louse is the smallest and darkest of the three; it lives best on the hairs of the pubic region and the arm-pit. The body louse crawls over the body, principally on the upper part of the trunk; it lays its eggs in the seams of the clothing where it stays by preference after each feed; it has a nocturnal character and probably thrives best in low temperatures. It is the biological carrier of typhus and requires about eight days after engorging itself with the blood of a patient before it can inoculate a non-immune person. Anderson and Goldberger assert that the infected lice do not transmit the virus in their eggs. The port of entrance is very likely the skin, as Theobald Smith and Libman maintain; but surely the virus can produce the disease in the non-immune whenever it can find admittance to the endothelia of the blood vessels, regardless of the path of entrance. H. C. Michie holds with reason that the salivary glands of the louse contain the virus. Undoubtedly the infection is conveyed through the sting of the louse. Nutall, however, holds a contrary view; he believes that it is necessary for the infected louse to be crushed on the excoriated seat of the sting and its smeared blood be rubbed into the system, before infection can take place. There is no doubt that the infected louse's blood contains the virus, and probably if the said blood is rubbed into a non-immune person, infection takes place; but to maintain that infection can only take place thus, is incorrect. The louse is a soft body, crawling over a soft body; for it to be crushed, requires its being placed between two hard bodies; this is not the case with the scratching fingers and the body on which it feeds. The lousy kill their lice by picking them out and squeezing them between the thumb nails or between one of the nails and another hard body. Lice may be killed while scratching with the nails, provided they are stabbed with the sharp ends; but this requires the exact location of the parasite and the employment of one's eyes to get an accurate aim; it is very difficult for a person to see the parasite on his back or upper part of his chest in order to take a correct aim. Hence the assertion that infection can only take place by rubbing the blood of the infected louse at the site of the excoriated sting, is untenable. Moreover, a living proof of the fact that typhus is transmitted by the louse's sting, is found in the sad death of Dr. H. T. Ricketts, who was investigating the cause of the disease in Mexico City. While incubating lice, infected with typhus, in a test tube under his arm, a louse escaped and bit him; he developed the disease and succumbed to it.

Thus far, the louse has occupied the place of honor. Are there no other worthies deserving attention? Guineapigs and monkeys have been experimented upon with the virus of typhus with positive results. Very likely the germ of the disease has a biological cycle in different hosts. It has been noticed that where a locality was infected with the plague, typhus was absent, and *vice versa*. The rat trails dirt and filth is its habitation. The plague which afflicts rats with deadly effect is transmitted therefrom to man and *vice versa*. In physics no two objects can occupy the same place at the same time. Likewise in medicine, no two active diseases can affect the same part at the same time; this is a maxim of nature. Certainly one disease may supervene upon another; but then the weaker gives way to the stronger. Does the rat harbor typhus? This is a difficult query to answer at the present juncture; but experiments in that line would be worth the trouble.

Climatology.—Most American and many European authorities maintain that the body louse and consequently typhus thrive best in mild and cold climates, at high altitudes, and away from the coast; the opposite conditions are deleterious to the same. Anderson and Goldberger assert that the parasite and the germ live best between 12 deg. and 16 deg. C. (53.6 deg. and 61 deg. F.) and that a temperature higher than 20 deg. C. (68 deg. F.) acted adversely on the longevity of the body louse. Wilder confirmed their observations. Others declare that the temperatures between 16 deg. and 20 deg. C. (61 deg. and 68 deg. F.) are very favorable for the growth and propagation of the germ and parasite. Anderson observed that in Mexico, the disease and parasite have never been seen below an elevation of 5,000 or 6,000 feet. Thence he concludes that they are not prevalent in summer and fall; from the same observations, he deduces that typhus and the louse never prevailed in tropical and sub-tropical countries, except above a certain altitude. Others declare that they cannot live in an altitude lower than 2,000 feet. Some asseverate that a temperature of 55 deg. C. (131 deg. F.) for fifteen minutes will destroy the virus.

These assertions cannot be universal and absolute; they can only be partially true. Inhabited Egypt consists mainly of the Nile valley which is encompassed on both sides by low mountains and sandy hills that form the borders of extensive deserts. The Delta extends from Cairo to the sea, forming one extensive, triangular plain, dotted with cities, towns, and villages; it is intersected by the Nile and its ramifications. Southward from Cairo, the valley narrows; its width varies from a mile or less to several miles between Cairo and the first cataract at Aswan. The general slope of the valley on both sides of the river downward is 10 centimeters for each kilometer; it is likewise 10 centimeters for each kilometer receding from the river toward the flanks; the slope on the river's surface is only eight centimeters for each kilometer downward. The banks are thus higher than the land further away; they are likewise higher above

the water's surface the further one goes up the stream. These distinctive features have been brought about by the gradual alluvial deposits. The country being surrounded by scorching deserts on both sides, is naturally hot; its climate is tropical, the maximum temperature ranges from 25 deg. to 45 deg. C. (77 deg. to 113 deg. F.) in the shade during the summer months. Occasionally it may rise to over 50 deg. C. (122 deg. F.) in such places as Aswan where in July, 1906, it rose to 53 deg. C. (127 deg. F.) in the shade on the left bank of the first cataract. Alexandria is a coastal city with temperatures often exceeding 30 deg. C. (86 deg. F.); it is but a few feet above the sea-level. Cairo is about 180 kilometers from the sea; its altitude is about 18 meters or about 59 feet. Maghagha, Minia Province, is about 338 kilometers from the sea; its altitude is approximately 33.8 meters or about 111 feet. Aswan is about 920 kilometers away from the sea; its altitude is about 92 meters or about 302 feet.

Typhus has been raging through the summer in many parts of Egypt; Cairo and Alexandria being heavily afflicted; in the latter part of July and the early parts of August, Cairo, with its temperature ranging between 30 deg. and 40 deg. C. (86 deg. and 104 deg. F.) saw many cases. A friend received a letter dated the end of July from Aswan, telling him that typhus existed there. The journal *Le Progrès Egyptien* of August 4, says that the villages of Atniah and Tanbadi, Maghagha district, have been declared infected with typhus. From these facts it is plain that typhus occurs in extremely hot weather, at very low altitudes, in summer, and in coastal cities. The body louse likewise exists under the same conditions. On the 13th of last August when the temperature at Cairo was 34 deg. C. (93.2 deg. F.) in the shade, Mohammed Shakir was examined to determine his physical capacity; body lice and their young were crawling in abundance over the back, chest, and arms. Moreover, the body temperature is never below 36.5 deg. C. (97.7 deg. F.) the world over; yet the body louse exists on the body with the said temperature; this is another salient proof that the body louse lives comfortably well above the temperature of 20 deg. C. (68 deg. F.). Hence the Mexico findings are not universally applicable. Like every existing thing, the louse and the virus of the typhus can acclimate themselves.

Pathological Anatomy.—Decomposition sets in early after death; rigor mortis is retarded; the characteristic eruption remains in spite of death. In general, the aspect resembles that resulting from a profound toxemia with venous engorgement superadded; sometimes myocardial changes are found as a result of this. The blood is dark and its coagulation time is increased. Meningeal irritation and edema of the lungs are found. The lymph glands, liver, spleen, and kidneys are enlarged and congested; Bauer in one case found a hyperplasia of the lymph follicles in a nearly normal spleen. Welch was the first to find the marrow of the femur red; he believed that the organisms multiplied there; this was probably due to the secondary effects. Proescher correctly holds that the germ first proliferates in the endothelia of the blood vessels, that it multiplies there and not in the blood stream, and that thence the infected endothelia are abundantly exfoliated into the blood. By some it is maintained that the bacteria are thrown into the blood only from the fifth day on; but they very likely appear about the second day. Fraenkel has observed peculiar alterations in the small cutaneous arteries where a sort of a periarteritis nodosa occurs. Bauer found the characteristic changes in the spleen, kidneys, stomach, intestines, thyroid, and all the other organs; he is certain of the correlation of the spleen's condition and Fraenkel's skin lesions; he also confirms the changes in and around the intima of the arteries in every organ.

The red corpuscles and their hemoglobin are increased; leucocytosis is present. Michie states that the white corpuscles vary from 18,000 to 50,000, that the polymorphonuclears form 90 per cent. and that the lymphocytes and the large mononuclears are decreased. E. C. Hart, on the other hand, holds that the relative and absolute increase in the large mononuclear cells, is enormous. The eosinophiles are often absent.

Course and Symptomatology. — Typhus is a disease of almost all climates, seasons, and altitudes, as has already been shown, though it is more prevalent in moderate temperatures. Its virulence varies from the attenuated form described by Brill in New York, to the severe types witnessed elsewhere.

Generally one attack confers immunity for life. Several types have been described under different names; but in reality they are only modifications of the same underlying cause. Naunyn considers typhus to be a syndrome rather than a disease; Furth endorses this theory; however, this is improbable, as the different forms met with are but different manifestations of the same disease, the difference being due to the different predominating sets of symptoms. The disease is generally sudden in its onset; often, however, slight prodromes precede it for a day or two; such are languor, anorexia, slight headache, and pain in the limbs. The course of the disease may advantageously be studied under (1) stage of invasion, (2) stage of eruption, and (3) stage of reaction.

1. The period of incubation varies from ten to twelve days; in rare instances it may be as long as seventeen days; some of old, such as Strümpell, held that in rare cases the incubation period lasted but a few hours; this is to be doubted, however. The disease is rapidly ushered in, commencing with a chill, sudden rise of temperature, severe headache, and pain in the neck, back, and legs. Great fatigue accompanies the disease; an early prostration, which is general, is characteristic. Pain in the loins and extremities is violent; the face is flushed; conjunctivitis often exists. Vertigo, spots before the eyes, and ringing in the ears are generally present. The tongue is dry, thickly coated, and often of a brownish dark color. Sometimes there is nausea; vomiting may occur; the bowels are usually constipated; tympanites and diarrhea are rare. Occasionally there is a nasal catarrh; a slight pharyngeal congestion may supervene; the respiration is increased in rapidity; now and then, there is some bronchial irritation; epistaxis is almost pathognomonic in combination with the other symptoms. The

pulse is accelerated and comparatively rapid; the heart is bounding; the absence of eosinophiles at this period is an unfavorable sign. The urine is scant, concentrated, and contains some albumin. The temperature in typhus is very characteristic; it is sudden in its onset and rapidly rises, sometimes in a few hours, to 40 deg. C. (104 deg. F.) or more; it remains high with very slight morning remissions. The skin is hot and dry. This stage lasts about four days; sometimes the eruption appears in its latter part.

2. The stage of eruption is characterized by three main features, viz., the skin eruption, the nervous symptoms, and the muscular affection; these are accompanied by a general aggravation of the whole picture.

The eruption from which the disease gets the name of spotted fever, supervenes about the fourth day; it may appear as early as the third or as late as the seventh day. The rash differs in different cases; it may be in the form of maculæ, petechiæ, or a marmorisation with all the gradations between. It generally appears about the axillary folds, the back, and the abdomen in the order mentioned. At first, the eruption is distinctly papular; then the papules become ovoid in form and vary in height from one-fourth to two-thirds of a millimeter; their color is a dirty pink; each seems to merge insensibly into the surrounding skin. On pressure they fade but do not disappear; sometimes the skin is diffusely reddened between. These spots are deeply seated, resemble subcuticular mottlings, and often simulate the rash of measles; as the disease advances, they frequently coalesce. In the very severe cases the rash becomes hemorrhagic about the second day. As a general rule, the face, palms, and soles usually escape the rash, though occasionally the palms and soles may be affected; the rash has even appeared below the ears. It reaches its full efflorescence about the eighth day; the papules assume a more rusty pink color with central hemorrhages. In some cases, the eruption is scanty or even wanting.

From the start the nervous system is deeply upset; when the eruption reaches its height, the headache begins to wane but the whole sensorium of the patient becomes more profoundly involved. Delirium sets in; this is either wild and active or low and quiet. In the active form. which is expansive, the patient may quarrel with and beat his attendants; he may suddenly jump from his bed or even attempt to throw himself from the window. In the quiet form, the patient mutters to himself and raves without any clear expression of ideas; his speech becomes incoherent. He becomes oblivious of what happens about him; stupor now may set in. The original somnolence is soon replaced by wakefulness; unconsciousness supervenes, when the eyes become wide open and staring into vacancy.

At this stage, the entire muscular system is so affected with prostration that the patient falls as a loose, helpless heap with trembling lips and limbs. Carphologia is often very marked; subsultus tendinum increases. The pulse becomes weaker and more rapid; there is a dusky appearance of the whole body; sometimes cyanosis is superadded; this is most marked about the lips and nails. Involuntary evacuations of the bowels and bladder may occur. Enlargement of the spleen is marked. The temperature remains high, generally above 40 deg. C. (104 deg. F.), in all severe cases; the morning remissions are slight, usually less than a degree Centigrade. Sometimes in favorable cases the perturbatio critica occurs on the seventh day. On the whole, in the latter part of this stage, the patient shows symptoms of profound toxemia with all the signs of pending dissolution. This desperate condition in the nonfatal cases, ushers in the third stage.

3. The stage of reaction or decline sets in about the thirteenth or fourteenth day of the disease; occasionally it may set in as early as the twelfth day or as late as the fifteenth. In the favorable cases, the reaction is characterized by a crisis, the temperature dropping suddenly to the normal or even subnormal in a few hours or less; the patient then enjoys a restful sleep and all the discouraging signs fade away as by magic. In some cases the temperature rises slightly on the following day; but it soon sinks to the normal. There is no other disease where the transition from extreme illness to health is so sudden as in typhus fever. After the crisis, convalescence sets in and lasts from two to four weeks, when complete recovery is attained.

As to the cause of the crisis, Olitsky in conjunction with Plotz and Baehr, declared before the New York Academy of Medicine in 1915 that the blood forms antibodies against the small, Gram-positive bacillus and that opsonins, precipitins, agglutinins, and complement fixing bodies develop in the blood of typhus patients and appear only shortly after the crisis, being absent during the fever; according to the same, the crisis is due to the activity of the cells and not to the sudden destruction of the bacteria. The last assertion is unsustainable. Fevers are due to the toxins of the causative germs; the blood produces an antitoxin to neutralize the circulating toxin; thus we have two forces arranged against each other, viz., the invading germs with their toxins and the white blood corpuscles with their antitoxins. As the conflict goes on, both continue producing their war materials of toxins and antitoxins; in the fight, the white corpuscles, the phagocytes, seek to destroy, envelope, and digest the bacteria; it is only when the latter are overcome that recovery takes place. As long as the intruding germs are not destroyed, they continuously discharge their toxins into the blood stream and maintain the fever; thus no crisis can take place as long as the germs are capable of producing their toxins. On the other hand, the view that the crisis is solely due to the destruction of the bacteria is equally untenable, for if the invading germs were destroyed without the neutralization of the already existing toxins, the fever would still remain and would disappear only when the poison was eliminated. What really takes place is probably this: By a final and supreme effort, the vital forces produce a sufficient amount of antibodies through the activities of the cells; these antibodies neutralize the floating toxins and probably paralyze the bacteria; at the same time the germs are destroyed by phagocytosis. The absence of the antibodies during the fever can be explained after Weil's theory in connection with pneumonia; he showed that during that disease the antigen was present in such large amounts tha

it bound the antibody; after the crisis with the disappearance of the antigen, the antibody could be found. And so it is with typhus; the antibodies appear only after the antigen has disappeared with the crisis through their preponderance.

The picture drawn so far is that of a case of moderate severity that ends favorably. However, there are many grades and shades of variations, with the abrogation of many of the severer symptoms in the light cases and the aggravation of the same in all the graver cases. In typhus exanthematicus levissimus the entire course varies from 5 to 8 days. In some of the cases the temperature does not fall by a typical crisis; the descent in such casis is more or less prolonged, but is always more rapid than in typhoid fever. Endemic typhus resembles the epidemic form on a reduced scale; it is milder and more attenuated. This is but natural, since constructive nature builds its defensive barricades to obstruct the intruder and reduce his virulence. Brill says that the headache in the endemic form is progressive to the end and that it recedes to the background at the end of the first week in the epidemic type.

In the fatal cases, no crisis takes place; the general symptoms become worse; the two heart sounds become alike; the urine is decreased or suppressed, with an increase in the amount of albumin; the eruption becomes more profuse and bloody, assuming a darker color; the temperature shoots up; there is a leucocytosis with a complete suppression of the eosinophiles. Hematogenous jaundice sets in, first appearing in the conjunctiva; the lungs become edematous; mucus accumulates in the pharynx; soon profound stupor crowns the scene, when the patient dies of toxemia. If the case is very severe, the patient may succumb in the first four days; in malignant cases, death may occur on the second or third day. In cases of less severity death occurs from the ninth to the fifteenth day. Gangrene of the fingers, toes, nose, and the scrotum occasionally occurs shortly before death. In some instances the patient dies after the crises as the result of the intense exhaustion supervening.

Complications in typhus are not very frequent. However, otitis, parotitis, bronchopneumonia, pleurisy, furunculosis, purulent cellulitis, dysentery, icterus, and bedsores may occur.

Diagnosis.—In enumerating the distinctive clinical marks of typhus the following points of Hort are worth bearing in mind: (1) the characteristic rash; (2) the peculiar smell of the skin; (3) previous cases to which the case may be traced; (4) the profound toxemia and stuporous condition in severe cases; (5) the critical drop in the temperature; (6) the intense blood infection; (7) the severe involvement of the muscular system; and (8) the profound involvement of the nervous system, with such symptoms as delirium, tremor, somnolence, stupor, coma-vigil, and maniacal excitement.

Typhus may occasionally be mistaken for other diseases such as malaria, relapsing fever, meningitis, etc.; but the principal disease with which it is apt to be confounded is typhoid fever. The following are landmarks that will steer one into safety: (1) Typhus is more sudden and rapid in its onset; (2) it is generally accompanied by a rigor; (3) the nervous symptoms are earlier and more severe; (4) the pain in the loins and limbs is severer; (5) the typhus lasts about a fortnight and rarely 17 days; (6) the fever drops by crisis; (7) in typhoid the rash is far more limited and never becomes petechial; (8) typhoid lasts from three to four weeks, paratyphoid excepted; (9) the temperature falls by lysis in typhoid fever.

The laboratory tests are numerous and have followed the different evolutions in the study of the disease. However, the following may summarize the principal views: (1) The presence in the blood films of large diplobacillary and diplococcal organisms; the presence of the same in fresh urine; (2) according to Hort and Ingram, the centrifugalized fresh urine contains minute Gram-positive, Gram-negative, and pleomorphic organisms; the same can be isolated and cultivated from the blood and cerebrospinal fluid; a culture of these organisms or of fresh typhus blood injected into bonnet monkeys gives rise to the disease; (3) Olitsky, Denzer, and Husk found that the agglutination tests were negative in the early part of the disease, occasionally positive at or near the crisis, and always positive after the crisis; (4) the urine may give a positive diazo test; (5) the most recent and positive reaction in the determination of typhus is the Weil-Felix reaction with the Proteus (x 19); this is an agglutination test and Friedberger looks upon it as a reaction of the organism against the pathogenic agent itself; (6) H. Kreuscher advances another agglutination test for typhus; he found one of the pyocyanic group to be electively agglutinated with the blood of typhus patients; under different conditions, the agglutination remained unchanged; this germ offered the same biological and bacteriological characters as the Proteus (x 19).

Prognosis.—This largely depends on the severity of the attack. A drop in the temperature about the seventh day and the increase of the eosinophiles and the large mononuclear leucocytes are favorable signs. The absence or marked decrease of the eosinophiles is a signal of danger. Recently it has been claimed that no cutireaction occurs during the febrile period of exanthematic typhus; but the MEDICAL RECORD of last March reported that Dumitresco-Monte experimented on 109 cases with crude tuberculin, 1-1000 solution; in all the cutireaction was elicited; his conclusions may be summed up thus: "A positive reaction in a febrile or defervescent or convalescent patient is a good prognostic sign. Conversely, if the reaction is negative after defervescence, the general state of the patient showing no corresponding improvement, the outlook is gloomy, and if reaction continues in a convalescent who has developed a febrile complication the prognosis must include the possibility of a fatal issue." As to the exact percentage of deaths, it is difficult to make any statement; in some epidemics it has been as low as 2 per cent; in others it has been as high as 70 or 80 per cent.

Prophylaxis.—Vaccine therapy has been tried with little success so far as a preventive measure. Recently P. Neukirch has experimented with a serum derived from typhus cases as a preventive against the disease; he prepared his serum by shaking it with chloroform; of this he gave two doses, each of 2 c.c., at an interval of two or three days. This also has not yet proved its worth; it would

not be surprising, however, if a prophylactic vaccine or serum were found some day. The most efficient measures for the present are the eradication of the causative factors of the disease. The following general rules should be strictly adhered to: (1) every positive or suspected case should be reported as early as possible to the health authorities concerned; no concealment should be allowed; the evil should be combated from the very start; (2) complete isolation must be adopted; those affording to be treated at home should be kept in an upper, well-aired chamber bare of all furniture except what is absolutely necessary; (3) those who cannot afford to have themselves treated at home should be removed to a hospital specially set for the purpose; (4) all contacts and suspects should be registered on a special list and seen daily for at least 12 days, or for 17 days, according to Pfeiffer; (5) contacts and suspects who leave for another locality should be traced and the health authorities of their destination informed, so that they may be made to complete the period of observation; (6) the house must be thoroughly disinfected after the patient's cure or death; everything should be removed and disinfected; flushing the place with sublimate, closing up vermin holes, whitewashing, and fumigating with formaldehyde are excellent measures to adopt; exposing everything to the sun and fresh air is an efficient adjuvant.

Our chief efforts, however, must be directed against the louse and a vigorous anti-louse campaign must be instituted from the very start to reduce lice infestation and destroy the parasites with their nits on the bodies, clothing, and bedding of all cases, contacts, and typhus suspects. Those visiting typhus patients should wear short trousers and skirts in order not to get lice. Cleanliness is the foundation stone in avoiding the louse and typhus.

Insectides: A minute's immersion in gasolene or any of the paraffin bodies destroys lice and their nits; benzene, toluene, and acetone are equally effective. Methane, ethane, ethylene, and their derivatives are lethal to the parasite; chlorine and its derivatives may be used with advantage; 40 parts of anis oil and 60 parts of pure alcohol is a good mixture to use. Sulphur, formaldehyde, ethereal oils, and oil of turpentine are excellent. Dichlorobenzol is a useful paraciticide; ammonia, chloroform, and tobacco smoke have destructive powers over the nits. High pressure steam for disinfecting portable and personal belongings is most effective.

In heads infested with lice the hair should be clipped off and burned; olive oil and kerosene in equal parts may advantageously be applied to the scalp. For the body louse a complete change of garments is necessary; the clothes, bedding, and other articles harboring the parasite should be thoroughly boiled or subjected to high pressure steam; a 25 per cent. mixture of dichlorethylene or trichlorethylene in vaseline is a good application to use on the body after the change of apparel. To get rid of the crab louse the infected region should be shaved and blue ointment applied.

Treatment.—Typhus has no specific treatment. Plotz prepared a vaccine; vaccines of the Proteus (X 19) have been produced, but so far they have not proved their utility. The handling of a typhus case crystallizes into the symptomatic treatment. The following points may be helpful: (1) absolute rest in bed is essential; (2) proper nursing should immediately be instituted; (3) the patient's room should be tidy and airy; (4) quietness about the patient is of prime importance; (5) the patient should be given plenty of refreshing liquids throughout the disease to wash away the toxins; (6) hydrotherapy and ice to the head should be very frequently resorted to; (7) symptoms are to be expectantly dealt with; (8) solid food that can be easily assimilated may be given as soon as the tongue begins to clear; (9) the patient should be kept in bed at least a week after the pulse has become normal.

141, RUE ABBAS.

INFLUENZA—A COMPARISON.*

By SIMON BARUCH, M.D.,

NEW YORK.

WATER has always been the therapeutic stepchild of medicine, being bandied about since the time Hippocrates first recognized its merits in "De Aqua et Locis." Medical history demonstrates, as clear as day, that the rise and fall of hydrotherapy was always contemporaneous with the rise and fall of intelligence among medical men. Hippocrates was without doubt a brilliant medical mind, for his axiom that Nature cures is to-day the foundation of the best therapy. Of all the remedial agents in vogue in his day, water appears to be the only one that has survived the vicissitudes of changing doctrines. Indeed, during my own career of fifty years the most active remedies have come and gone out of vogue, but water appeared firmly entrenched until the coal-tar antipyretics competed with it as a temperature-reducing agent in the latter decades of the last century. That this rivalry was destined to result in the defeat of water would have been ascertained earlier had medical men borne in mind that Hippocrates wrote, many centuries ago, "cold water warms, warm water cools." If you take away with you this afternoon no other thought than this true apothegm, I shall be content. "Write it upon the doorpost of thine house and upon thy gate," says the good book about the Ten Commandments. And I say to you that the constant remembrance of this absolutely true dictum of the Father of Medicine will prevent your falling into the pitfalls that have misled and are to-day misleading the ablest men of all countries. Following the teaching of Hippocrates, which has been confirmed by experience, when I am asked for a temperature-reducing bath I advise a tubbing of half an hour or more in water at 100° F. and not a bath of 60° F. For I have not forgotten that physiology teaches that whenever the organism is attacked by cold it immediately sets in motion the heat regulating functions to compensate for the loss. Bear this fact in mind, if you please, and you will never injure your patients nor produce shock or collapse. When by reason of this fatal teaching of the Germans cold baths had fallen into deserved desuetude as an antipyretic, they were rescued for a time from entire abandonment by Ernest Brand, a physician of Stettin, who during the

*A lecture at the Walter Reed General Hospital, Washington, D. C.

Franco-Prussian war treated typhoid fever among the French prisoners of war with cold baths so successfully that Glénard, a professor of medicine in Lyons, who was among these prisoners and assisted Brand in treating his fellows, introduced it in France after the war. Here it became established, especially in Lyons, while in Germany it was discontinued probably because Brand was not a professor in a university. It would appear that the same junker spirit that has brought ruin to Germany hampered the advancement of this life-saving measure, for Curshman, whose clinic in Leipzig I visited in 1902, treated his typhoids with baths at 85° F. with a mortality of 15 per cent. despite the fact that Brand's statistics gave 3 per cent. mortality in a large number of cases. The statistics of this therapy are the most instructive and reliable in medicine. Of 120,000 cases gathered under regular treatment of all kinds, 20 per cent. died, while of 7,426 cases treated with strict Brand baths only 4.24 per cent. died. Loomis of New York stated that the mortality of typhoid fever in New York City hospitals was reduced 50 per cent. by this treatment. And W. Gilman Thompson stated in his textbook (1902) that in the Presbyterian and other hospitals typhoid mortality had been reduced from 15 to 6 per cent. by the strict Brand bath—70° F. with good friction every three hours when the rectal temperature was above 102.5°. Just as after Hippocrates and Celsus the water treatment went into desuetude, so is it neglected at the present time, for in the very hospitals in which it had been most successful it is now "more honored in the breach than in the observance." Some day I shall try to present the difference in mortality since the abandonment of the regular bath treatment. Here you observe clearly a fault of *omission.*

That we are guilty of a fault of *commission* at the present time when the disregard of the maxim of Hippocrates destroys life, I shall demonstrate to you beyond cavil from undeniable records. In 1895 there was an epidemic of sunstroke in New York City which destroyed 648 lives. It appears from the statistics of Alexander Lambert that 25 out of every hundred of these could have been saved by due regard of the teaching of Hippocrates that cold water warms and warm water cools. For in the St. Vincent's Hospital, under the late Dr. O'Dwyer, the mortality was 6 per cent. in 197 cases of hyperpyrexia treated with cold affusions of tap water, sometimes iced, while in Bellevue Hospital, where the patients were treated with iced baths, the mortality was 33 per cent. And yet nearly every textbook advises to-day that in sunstroke the first indication is to reduce the temperature and the best remedy is very cold baths.

Far be it from me to cite these sad historical facts in a spirit of criticism. My aim is to "learn from the faults of yesterday the wisdom of to-day." The fault lies with those who have not learned the lessons of the history of medicine. It may be claimed and granted in the first instance (Brand method) that it is the right and privilege of physicians to accept or not the statements of Brand and others who may be regarded by them as enthusiasts in hydrotherapy. But it is not the right and privilege of any humane physician to continue the ice bath or similar homicidal practice in sunstroke when the facts have been published by men who are not advocates of hydrotherapy and are known to be fair clinicians. For twenty years people have been dying from sunstroke because of *excessive* use of cold water. I sometimes wonder if the mortality from influenza may not be partly accounted for *by the neglect of water.*

A comparison between water and drug treatment in this disease, which has brought more sorrow and death into households than any other visitation of modern times, may serve to save lives. The fatality of this scourge has perhaps been larger than it should have been in view of our knowledge of the fact that the disease manifests itself as a toxemia, the chief force of which is exerted upon the vasomotor system, as indicated by the uniformly slow and compressible pulse, etc. Let us see whether or not the treatment in vogue is justified. I quote verbatim from a report with the caption "Therapeutics of Influenza," in one of the most reliable medical journals. "Influenza was treated largely symptomatically. Acetylsalicylic acid 15 grains every three hours until symptomatic relief is secured." Another journal reports: "In severe cases the fever and other evidences of profound intoxication call for the salicylates, one of the synthetic antipyretics, or quinine!" From an able article in the latter journal I quote, "Sudden death in the epidemic of influenza has resembled in some respects an overwhelming toxemia affecting the vasomotor system." These ideas are reiterated in all the literature at my command and in communications with army and navy surgeons and other colleagues. Do they not reecho the slogan of other days, when *typhoid fever was also treated "symptomatically,"* to the detriment of the patient?

The unanimity of this therapeusis in typhoid fever and the fatality which led to its abandonment emboldens me to sound this note of warning: May not history be repeating itself? I trust that the error of the present coal-tar drugging of influenza may be revealed more quickly than was that of typhoid fever and lead to its abandonment.

"Warm packs may give relief, although in the ——— Hospital hydrotherapeutic methods failed and were discarded." Note, if you please, first the indefiniteness of this prescription of warm packs. I have taken the precaution, before appearing here, to ask one of your nurses what she regarded as "a warm pack." She replied: a woolen cloth wrung out of water as warm as the patient could bear. Now imagine the patient writhing under a temperature from 100° to 106° F. when this "hydrotherapeutic procedure" was applied. Would it reduce his fever? Would it help his handicapped heart? Certainly not, for we know that the warm moisture would prove to be a poultice that would relax the cutaneous vessels and render the skin wrinkled and cyanotic, and thus add to cardiac asthenia. Shall other "therapeutic methods be discarded because an improper one failed? A similar illogical course has, unfortunately, caused the discarding of the cold friction bath in typhoid fever. I ask you to read my "Don'ts" in Hare's "Practice of Medicine," which point out the proper method of changing the bath when unfavorable manifestations appear from too low temperatures, etc.

"When pneumonia develops," goes on this therapeutic lesson, "every effort must be made to provide

for an adequate supply of intake of fluids, and nourishment must be given in fluid form to a large extent." At another place it is stated: "In the cases of secondary pneumonia, many of which resulted fatally, the chief conditions to be combated are the severe toxemia and the vasomotor depression. The toxemia may be combated by the usual methods—getting fluids into the system by proctoclysis and hypodermoclysis, securing elimination with large doses of salts, calomel, venesection, oxygen, etc." "With any indications of the failing heart stimulants are indicated." How these latter remedies remind us again of the discarded practice of our forefathers in typhoid fever! I leave you to judge, also, if your physiological knowledge will sanction this waterlogging of the system and this overburdening of the already handicapped heart with the elimination of all this fluid.

Now let us see how the *judicious* application of water in this toxemia would operate, so that you may in future pandemics of this infectious disease bear it in mind and thus save life and relieve suffering. Water below the temperature of the skin is a thermic irritant. That its therapeutic action is rationally explained on this theory is evident in its application to the stillborn infant, which, as you and I have been taught, and have successfully practised, must be sprinkled with cold water; if not effective, it must be dipped in cold water, or, if necessary, be alternately immersed in cold and hot water. The result is, as the merest tyro in medical practice knows, the conveyance of the excitation of the sensory terminals in the skin to the central nervous system and its reflection upon the respiration and circulation.

Now, this is a lesson in hydrotherapy, an epitome of the whole subject, in that it not only offers a practical demonstration of the theory but also of dosage and of clinical proof. The small dose of cold water in sprinkling being insufficient, we were instructed in our student days to apply a larger one —the dip of the entire body, or a still larger "dose" in the contrast dipping, which raises the sensitiveness of the skin nerves and vessels by warmth, so that the subsequent cold may act more intensely. Now, if we were to apply this method in the toxemia of typhoid fever, or in opium poisoning, "the dose" would be far too small to arouse the nerve centers. Between these extremes, however, there are, happily, mild measures, each acting in proportion to the contrast between the skin temperature and that of the water, the area of skin treated, frequency of repetition, etc.

I would apply this "dosage" and did apply it in a few consultation cases (two in this hospital) in accordance with the conditions to be met—not, however, as a symptomatic remedy as the drugs above referred to were applied, but as a refreshing procedure by which the toxemic condition would be counteracted if not neutralized, as I and others have observed a thousand times in typhoid fever and other toxemias. The disease being of short duration, unlike typhoid, I advised friction baths of 90° Fahr. reduced during ten minutes to 80° Fahr. and repeated every four hours in some cases when the patient was not sleeping naturally. The patient was placed upon a small rocking-chair on which a blanket and old sheet had been spread, was drawn backward to the bath room, and replaced after the bath, which had been given with friction. The bath was followed when cautiously rising by an affusion of a basin of water at 75° Fahr. over the shoulders. He was returned to bed. If the temperature was over 102.5° rectal, he remained in the sheet and blanket till dry, otherwise he was quickly dried and placed on the other side of the bed. So soon as he was warm a compress of two folds of a linen towel without fringes, of a size to cover the anterior part of the body was wrung out of water at 60° Fahr., a flannel binder was slipped under him, the wet compress snugly applied and secured with the flannel band. The sheets were kept dry with towels beneath and above the binder. This compress was renewed every hour, when its edge felt warm. The result was renewed stimulation and consequent refreshment when the compress was applied and some antithermic action by evaporation of water through the flannel, all of which meet imperative indications in which the coal tar drugs not only fail but accentuate. In two cases the compress alone sufficed.

You now have the comparison in technic and effects between the drug and the water treatment. I grant that the former demands less care, but it is depreciating and handicaps the patient, while the wet compress begun early enhances his resisting capacity. This should be the main object of therapy in infectious diseases.

Millet, the great painter, was asked how he mixed his paints to produce such wonderful coloring. He replied, "with brains." This applies to the application of water in disease. In fact, no remedial agent is worthy of our confidence unless it meets three conditions: (1) that it must be readily obtainable; (2) that its rationale must be physiological; (3) that clinical proofs of its value are accessible. Water fulfills all these conditions—at least as well as most drugs. Why, then, is it not in common use after its exploitation by the most brilliant men for twenty-three centuries? Among other reasons is the lack of instruction in our schools and the fear of shock. There are two conditions greatly misunderstood in hydrotherapy, *shock* and *reaction*. The so-called *shock* from cold water is an unpleasant surprise to the cutaneous nerves, which is taken cognizance of by the brain. *Reaction* is usually regarded as requiring a reddening of the skin. The latter is really not necessary, so long as the patient does not feel chilly fifteen minutes after the treatment.

It was my intent to demonstrate the wet pack this afternoon. This procedure had been filmed here by the Surgeon General's Instruction Laboratory. By courtesy of Commander Edward Old of the Hospital Ship *Solace* it was put on the screen on his ship, after which I had the honor of explaining its value as a hypnotic. A few days ago Dr. Old wrote me as follows: "During the recent epidemic of influenza a number of the pneumonia cases were delirious and very restless, having to be restrained, these symptoms being beyond control by the use of drugs. Some of the men would remain awake day and night, the whole time in marked delirium, and the condition was one such as at times tries the nerves of physicians and attendants. Remembering the film which you showed us and your dis-

course on the benefit of the wet pack in controlling insomnia, we tried the treatment so strongly advocated by you, on the above class of cases, and I know that you will be pleased to hear that in nearly every case it was found most successful and of marked benefit to the patient."

This is surely a demonstration by the Surgeon General's Instruction Laboratory in saving life and comfort.*

In chronic and subacute cases in which appetite and digestion need to be enhanced, the addition of neurovascular training induces more rapid improvement. In domestic practice the patient may be seated in an empty tub with the outlet closed or in rural dwellings in a washtub with feet outside. Water dipped from a bucket with a basin is poured from the latter over the shoulders and chest and back, its temperature beginning with 90° Fahr. and reduced daily one or more degrees so long as reaction is good, until 60° Fahr. is reached. Then larger quantities are used, beginning with 80° Fahr. and lowering daily, unless reaction be poor, when the same temperature is continued but only half the number of basins. After drying, the patient is sent out doors. In institutions like this great hospital the skin is warmed in a hot-air bath. This is followed by a fan douche at 90° Fahr. for two or more minutes, which is reduced daily as above. The patient is sent into the fresh air after treatment. This is termed neurovascular training because the nerves and vessels of the skin are inured to lower temperature and increased duration as are the arm muscles in dumbbell exercises. The results comprehensively termed "tonic" will aid powerfully in the reconstruction efforts of this great hospital, when added to other measures now in vogue.

If I have succeeded in impressing upon you the importance and simplicity of hydrotherapy by the comparison of the proven effects of drugs and water in disease and if I have induced you thereby to study and practice the application of water in disease, I shall regard the hours I am spending in this great hospital as profitable.

51 West Seventieth Street.

THE TWO MOST IMPORTANT SIGNS IN CHRONIC APPENDICITIS.†

By ROBERT T. MORRIS, M.D.,

NEW YORK.

A boy came running into the office one day and asked me to hurry and see Louis who had appendicitis. "Who is Louis?"

"My brother."

"How do you know that he has appendicitis?"

"Louis and I were throwing snowballs and he had to stop because he had so much pain in his stomach. Mother called in Dr. X. who said that Louis had eaten something that had gone wrong with him. After the doctor had given him a prescription and had gone home, Louis complained so much about the pain in his stomach that I pushed on his appendix to see if he had appendicitis. When I did that he yelled right out, so I went for the doctor again and told him that he must come back because I had found that Louis had appendicitis. Doctor came back and said, 'Yes, that is so, go down and get Dr. Morris.'"

That was a good many years ago. The day has passed when we have to leave the diagnosis of acute appendicitis to children. Almost any sort of a doctor now makes the diagnosis of acute infective appendicitis, but that does not relate to a commoner chronic lesion of the appendix as I observe in consultation. The acute infective disease is more emphatic in its demonstration and attracts attention more quickly, consequently we have rather come to think in terms relating to an infective process whenever an "itis" of this vestigal organ is up for discussion. There is another infective lesion besides intrinsic infective invasion of the organ. An extrinsic infection proceeding from a Falloppian tube or from the peritoneum or from some other organ or structure may involve the appendix incidentally, the latter then going on with its own set of symptoms.

Of the four common forms of appendicitis two are infective lesions and two are irritative lesions. Among the irritative lesions what we may call syncongestive appendicitis is the least important. There is a congestion of the appendix synchronously with congestion of other structures in the vicinity as a result commonly of some interference with the blood or lymph circulation. The appendix feature comes into evidence because the inner coats of the appendix trying to swell within the tense outer sheath become more or less pinched and painful. This is a very harmless form of the trouble and disappears when the congestion of neighboring structures has been relieved. The commonest of all forms of appendicitis is an irritative lesion, not an infective one, and it appears in fibroid degeneration of the organ. The appendix is prone to undergo fibroid degeneration in most of us late in life, but in the neurotic neurasthenic group of patients early fibroid degeneration of this vestigial structure seems to appear very early as a stigma of arrested development, associated with other stigmata which the neurologist commonly discovers. Fibroid degeneration of the appendix probably takes the patient to the doctor's office more frequently than any other form of appendix trouble and this irritating lesion with its accompanying gastro-enteric features will often lead pretty good diagnosticians into mistaken diagnoses. Another irritative lesion of the appendix, not infective, is one in which the appendix has become involved to greater or lesser degree in scar tissue following some previous acute infective invasion. In this sort of a case nerve elements remain in scar tissue very much as they do in an appendix undergoing fibroid degeneration. It is because of the persistence of nerve elements that we commonly have chronic appendicitis, not infective in character, giving rise to disturbance which sends the patient

*Since the lecture was delivered, one of the staff of the Hospital had Lieutenant Danzer apply it in a case of pneumonia with good effect.

I was asked by a colleague who had on my advice observed the fine result of an hourly anterior compress at 60° F., if 85°, which he had applied in another case of influenza, would suffice, while the patient becomes inured to the shock. "Seeing is believing" did not appear true in this instance; the fear of shock prevailed.

†A paper read before the Medical Society of the County of New York on November 25, 1918.

to the doctor's office. The matter of differential diagnosis becomes important.

There are two chief signs upon which we may place dependence when looking for the culpable organ. These two points in diagnosis do not relate to acute appendicitis. Please keep that fact clearly in mind. When a chronic irritative appendicitis has registered its nerve impulses on certain sympathetic ganglia for a fairly long time the muscular coat of the ascending colon becomes wearied. This wearied ascending colon with lax muscular coat remains distended with gas most of the time and gives us what I call the "cider barrel sign." Percussion upon the left side of the patient's abdomen gives us a note reminding one of the cider barrel in October and percussion upon the right side of the patient's abdomen gives us a note suggestive of the cider barrel in March.

The other chief sign and the most important one perhaps consists in a hypersensitiveness at the site of the fused second and third sympathetic lumbar ganglia. The older anatomists spoke of the sympathetic lumbar ganglion, including several ganglionic structures, but the later anatomists commonly make five lumbar ganglia on either side of the spinal column in the lumbar region. Persistent nerve impulse from an irritated appendix appears to be registered selectively upon the fused second and third ganglia so that we have hyperalgia of more or less permanent character relating to this ganglionic point. If we press deeply upon the abdomen about an inch and a half to the right of the navel and a trifle caudad the patient speaks up when we are pressing upon this particular ganglionic point in cases of chronic appendicitis but he does not interest himself in this point particularly if we do not have chronic appendicitis. When I first made presentation of this point at the Academy of Medicine Dr. Robert F. Weir brought with him for the discussion a number of anatomical plates and argued that there might be some error in the observation because there was no direct nerve connection between the appendix and these lumbar ganglia. I then assumed that we might be dealing with the question of sensori motor synapsis by way of the spinal cord but Dr. Albert C. Geyser has made more elaborate explanation. It is his belief that the irritated appendix calls for a determination of blood to the vicinity and that regulation of the blood supply being dependent upon the sympathetic nervous system the sympathetic ganglia called upon most persistently become hyperesthetic. In any event when an afferent impulse is sent from an irritated appendix to a segment of the spinal cord an afferent impulse with two definite manifestations is manifested. One of these consists in sensitiveness of the skin in the Head zone for the appendix and the other and more important sign consists in hypersensitiveness at the sympathetic lumbar ganglionic point situated about one inch and a half to the right of the navel and a trifle caudad from that point.

In cases in which hypersensitiveness of the left lumbar ganglion is discovered on pressure we discount the importance of the sign relating to the appendix and look for some irritative lesion in the pelvis. The pelvic sympathetics gather and transmit impulses over such a wide distribution that both sets of lumbar ganglia may become hyperalgic but when the appendix alone is involved the right lumbar ganglionic sign standing alone becomes the most important one in differential diagnosis. If the first lumbar ganglion is involved, the one to the right of and somewhat cephalad from the navel we have Mayo-Robson's point relating to the pyloric and gall-bladder region.

616 Madison Avenue.

HEARING AND ITS REGULATION. ESPECIALLY IN MIDDLE AGE AND EARLY SENESCENCE.

By J. MADISON TAYLOR, A.B., M.D.,
PHILADELPHIA, PA.
PROFESSOR OF APPLIED THERAPEUTICS, TEMPLE UNIVERSITY, MEDICAL DEPARTMENT.

Hearing is next in importance to seeing. The brain needs to be aroused by hearing quite as much as by seeing, especially in circumstances of bodily peril. The ear must inform as to direction and distance as well as nature and quality of warning sounds. Acuity of auditory sensitiveness is a fundamental requirement; it should be preserved and kept in a high degree of efficiency through training. This training process may be of the simplest; an intelligent attention and differentiation through our ears to familiar and unfamiliar sounds.

Heedlessness is the foster brother of stupidity, and opens the gates for losses of valuable information; exposes one to incalculable losses as well as perils. Errors through inattention are unforgivable. The loss may be of impressions useful, minatory, pleasurable, or inestimable. The more you reflect upon it the more surely you will come to admit that no one can afford to neglect not only keeping one's hearing up to par, but equally training what one has of auditory capacity, so as to be always available and remunerative.

Just as there are some persons more largely influenced by sensations of sight, "eye minded," so are there others whose being responds more acutely to impulses received through hearing, "ear minded." Some delight in music, thrill to "the concourse of sweet sounds" whether these emanate from intentionally arranged sound producing elements or merely the more generalized, less defined auditogenic factors which go to make up that entity called by the rather exaggerated phrase "the music of the spheres," assuming by that is meant the composite sonorousness produced by widely acting movements.

Among collective resonant agencies may be reckoned the cadences produced by the wind, "Eolus" (*i. e.* "Eolian harp"), the breathings of nature, the passage of the wind through trees, shrubbery, "the wind among the barley," through rocky gorges, chimney tops, around the house, the sound of falling water, rain on the roof and the like. A grade above these sensory delights are the sounds from woodland creatures, insects, birds, "the lowing of kine." We hear of "the diapason of the great cities," of the many rippling waves of the sea (arithmon gelasme pontecon town).

Less agreeable or actually offensive sounds tend, on the other hand, to distress an over-sensitive ear, especially at certain times and under diversified circumstances and associations. If auditory distress be due to mere esthetic over-sentiveness or hyper-exaltation nothing need be said; if an element of aural abnormality exists then a careful exploration should be made, and that lesion should be remedied. However, a continuity of offenses through unescapable evil sounds may act as a serious strain on nerves and mind, inducing distress and damage. Often enough the resentment felt is merely a selfish attitude of mind. Here we approach the domain of erroneous habit formation which requires ethical education and self-regulation.

We have, as you will note, hinted at two opposite but pertinent grounds for educating the sense of hearing. Next we may allude to the gravity of losses in acuity of hearing so common as middle age progresses, also the urgent need for personal cooperation in any scheme of conservation or repair of hearing.

Hearing as a source of pleasure and profit, so my impression goes, is neglected much more than vision. We may except of course those whose special occupation or professional interests lie in the domain of sound production or reception. Few pay adequate attention to their auditory possibilities or unobtrusive impairments.

While not personally specializing in ear or throat troubles, these problems were brought sharply to my attention while serving for several years as assistant to the late Dr. Carl Seiler and also later in a special clinic of my own. An invaluable basis was afforded for observation as to the significance of visual and auditory competence in solving problems of personal conservation and reconstruction. I have frequently been able to discover beginning and occasionally long neglected or totally unrecognized causes of decrepitudes referable to defects in sense organs, which often acted as the chief agency in yet more urgent disablements.*

Of course if suspicious phenomena point clearly toward trouble in the ear and an expert is consulted, the difficulty will be recognized and alleviated. If not, it is up to whomsoever is advising, to exercise alertness as to possible sense organ sources of the difficulty.

A considerable number of chronic ear disabilities depend on a greater or lesser impairment in elasticity in the structures in or about the ear. These being overcome, or mitigated, more or less auditory competence is restored, as well as any associated distresses removed. A personal case will serve to illustrate the principles involved: Sixteen years ago the mother of two girls, trained nurses and experts in physical culture, had grown distressingly deaf. The best aurists had been consulted and informed her that chronic catarrhal states (otitis media) had progressed to a point where no relief could be expected. In order to test my convictions, I inaugurated, with the help of the daughters, a series of passive and active movements designed to restore elasticity to the tissues of the neck, the jaws, and the ear structures. The patient was then 69 years of age; she is now 87. A large gain was made in a few months which was estimated at 30 per cent. Of late this gain has shrunk, but still hearing remains far above what it was when we began.

The stimulus to make this trial grew out of my confidence in the efficacy of mobilizing and elasticising the structures of the neck and jaws. I had heard from Dr. Seiler in 1880 of a famous woman teacher of singing in Vienna, who had achieved surprising effects in enhancing vocalization by employing grimaces, mobilizings, and special jaw exercises.

An interesting review of a book by Herr Lantz of Vienna was given in the *Scientific American* for January, 1917, p. 671, on "the yawning cure for throat diseases." His method is based on that of Josephine Richter, a teacher of singing. The method is a combination of vocal and physical culture, particularized movements of the jaws which ultimately give the pupil astonishing control over the soft palate, muscles of the face, neck, and chest.

He quotes Helmholtz to the effect that flabbiness of the soft palate and back of the mouth acts as a damper upon the voice, hence tonicity of the controlling muscles of the face and throat is impaired or lost. This fact becomes of the utmost importance when abnormalities of the parts exist.

In an untrained throat, the soft palate and uvula hang limp and constrict the vocal passages which are further narrowed by prominent tonsils. The tonsils of a trained singer are retracted and strong; the uvula has disappeared, giving the voice clear passages and firm walls, hence an increase occurs in the volume and quality of phonation and vocalization.

The exercises of Herr Lantz are those of yawning which bring all the respiratory muscles of the chest into action, hence is the most natural means of developing them. He advises every one to yawn as deeply and frequently as possible, with the arms out-stretched, to change completely all the air in the lungs and stimulate expiration. One can teach oneself to yawn by suggestion and preliminary exercises in deep breathing. In each treatment 6 to 8 deep yawns are followed by swallowing. He warns that deep breathing may be overdone by persons with weak hearts. The obstacles which the yawning cure is alleged to remove are those which are useful in preventing the entrance of hurtful bacteria.

Fernet (*Semaine médicale*, March 15, 1911) discusses in detail the functional impotence of the muscles of the ear, the accessory role they may play in hearing, and the necessity for their reeducation. He refers to the great mobility of the ear in animals, and is convinced that a majority of people can,

*An illustrative incident which impressed me greatly occurred in my earlier years while assistant of the late S. Weir Mitchell. An elderly gentleman of great prominence in the industrial world consulted him and was referred to me for examination and history taking. He had suffered for years from an intolerable vertigo; had spent months in Europe, consulting diverse nerve specialists without relief. On his way home in the West, as a last resort, he stopped over to see what Dr. Mitchell could do for him. I had gone over him carefully, taking copious notes. After looking over these, Mr. Mitchell said, "Did anyone examine your ears?" On being answered no, he examined the ears and found in one a mass of wax and cotton pressed against the drum. This he removed, syringed out the fetid canal, and the next day all seemed well. Subsequently the patient remained a healthy and happy man.

by voluntary effort, move the ear upwards appreciably, as well as backwards and forwards. Duchenne has studied these muscles under faradization, and has shown that the muscles of the tragus and antitragus, of the helix and antihelix, all share in moving the lobe of the ear, and can even modify its shape. The effect is to favor the access of sound waves to the tympanum, and also to protect the ear against too strong impressions. The muscles of the middle ear are more important still. All these muscles, extrinsic and intrinsic, are innervated by the facial nerve, and the author suggests that, as there is a relationship between the contraction of the extrinsic muscles of the ear and those of the epicranium and face some similar relationship may exist between these muscles and those of the middle ear.

The extrinsic muscles of the ear, according to this author (Fernet), are capable of reflex contraction under ordinary conditions, and the action can be reinforced by voluntary effort. The act of listening intently stimulates the activity of these muscles. Acting on these principles the author suggests, in addition to massage and electrization, a series of auricular gymnastics such as movements of the scalp from before backward, this to be followed by relaxation and a reversal of the movement. Associated with these are to be made similar movements of the ear, which is dragged backwards by the epicranial, as well as by its own muscles. This is likewise done in the case of the other muscles of the ear, and finally without the aid of the epicranial muscles, the endeavor being to produce a sort of circumduction round the auditory orifice. It is necessary to proceed slowly during the seance, a short series of movements being followed by rest, as overfatigue might lead to giddiness.

The author recommends these exercises in the early morning for a period of time lasting from ten to fifteen minutes. Reflex movements are also to be encouraged by such means as listening to the ticking of a watch, and very gradually increasing the distance. The sustained effort of listening seems to exalt the auditory sensibility, whether from a succession of sound waves—which might not happen in the case of a single excitation—or because the extrinsic muscles of the ear assist in the manner described above. A defective ear must be encouraged and the tendency to listen always with the better ear avoided. This regularization and coordination of all the functions of such an organ as the ear results in more perfect development, and the author suggests that in certain cases of middle-ear deafness the muscles of the dilated Eustachian tube may also be beneficially acted on in this way, as they likewise are innervated by the facial nerve.

Summary, Conclusions, and Procedures.—The possibilities of improving states of neglected or impaired audition will thus be noted as encouraging. They consist in emphasizing attention and self-regulation of the patient to his function of hearing; in learning the direction and degree of under-development both in structure and function, or a combination of structural and functional neglect, inattention, and apathy, and improving the conditions.

The chief objectives are (1) to achieve conscious control over all parts concerned in hearing, direct and associated, *i. e.* in training of voluntary and semivoluntary structures, and (2) to direct intelligent attention, critical and helpful, to elaboration, cultivation, and refinement of the function of audition, to bring up to par all the latent powers which reside in the aural equipment as a whole.

Procedures: 1. Passive motions, manipulations applied to the structures; seize the concha with the encircled fingers, draw it up and down, backward and forward, round and round; in applying manipulation to the neck, the posterior scalp—which is usually found rigid and adherent, also to the dermal structures over the 2nd, 3rd, and 4th thoracic vertebræ (vasomotor subcenters) by pressure and relaxation, by lifting and pulling the overlying skin, and also by mobilizations of the joints of these vertebræ at corresponding levels by alternating pressures.

2. Making active movements of the jaws, opening widely as possible, rotating, side to side, forward and back; also in yawning and swallowing afterwards.

3. Active movements of the neck, to the right, to left, also thrusting the chin forward each time, then chin up vertically, forward, and back.

4. Inducing the patient to seize the back of his head with hands clasped and to bend far forward and down, then to push the hands back with the head (neck muscles) and repeat five or six times with increasing force.

The whole procedures occupy about six or eight minutes and should be repeated at least once, preferably three times daily.

1504 Pine Street.

BRAINS AND MILK.

By CASPER L. REDFIELD,

CHICAGO.

More than forty years ago I read an article by an eminent scientist of the day. I do not remember his name and I have forgotten the details of the article, but I remember its general drift. It was to the effect that Edison, in attempting to make a commercial incandescent electric light, was simply exhibiting before the public his ignorance of scientific principles. The answer is the incandescent electric lght.

That scientist knew more things than Edison knew, but he did not have so much brains—that term being used in its popular significance to indicate the mental power which accomplishes things. Since Shakspeare's time we have had other playwrights who knew more things than Shakspeare knew, but we have had none with brains enough to produce such imperishable literature.

In our recent international unpleasantness new men came to the front and old authorities were relegated to the rear. Those men who came to the front were not so much walking encyclopedias as they were men of brains. To be anybody, a man must have both accumulated knowledge and brains, but when real things are to be accomplished, it is the brains end of the combination which bulks large.

Whence come the brains which distinguish one man from another? Many persons think that such men as Moses, Columbus, Luther, and Lincoln were

raised up by divine power for divine purposes, and that Judas, Guy Fawkes, and Emperor William were mere tools in the hands of the Lord. Other persons believe that great men are "happenstances" which occur occasionally without any cause whatever. The eugenists, and the biologists upon whom the eugenists lean for information, say that a man with brains is such because he is descended from ancestors with brains. Let us examine this last.

During the past century we have had a good many Americans, who, if not exactly eminent, were very superior persons. A large number of these men are descendants of the New England colonists. If the picked superior men of the last century were such only because equally superior men existed in the New England colonists, then that band of colonists must have been extraordinary supermen.

Or, take the same thing on a broader scale. Since the beginning of the Christian era there have been many thousands of eminent men. All of those eminent men had ancestors living in the first century before Christ. If the brains in that one century were equal to all of the brains in the nineteen centuries since, then the men of that century must have been wonderful men.

Every once in a while there arises an exceptional man. The exceptional man is superior to his great-grandparents. If he were not superior he would not be exceptional. We cannot say that the man with brains is such because he had one or more ancestors with equal brains. Follow any such doctrine back step by step and it lands us in the doctrine of special creation with Adam and Eve, equal to anything which has existed since.

Mental power is inherited. A man cannot inherit from a parent something which the parent did not have. To assume that a man can be born with something which he did not inherit is to assume special creation to be a continually operating thing. It is generally conceded that man is descended from a common ancestor with the ape, and that that common ancestor was mentally inferior to the men of to-day—had less brains. To get such improvement without special creation it must be possible for a parent to transmit more brains than he inherited.

If a parent is to transmit more mental power than he inherited, then he must acquire that mental power in some way after he is born and before he reproduces. The one and only way to acquire mental power is to be mentally active, and to acquire much mental power a man must be mentally active for a long time. If this is the process by which mental power is built up so that a man may transmit to his offspring more than he inherited from his parents, then men with extraordinary brain power should be sons of old men, because only old men have been mentally active for a long time.

A general view of the situation shows that the man of great brain power does not arise suddenly from parents of inferior stock, but that he is the culmination of several successive generations of gradual improvement. This fact has been noted by Galton and others, and is well established by a great mass of evidence. Hence, if the real source of mental improvement from generation to generation lies in acquired mental development before reproducing, great men should arise from several successive generations of old parents.

As a matter of fact that is the exact way in which men of great brain power do arise. Such a man is sometimes the offspring of relatively young parents, but he is never the result of successive generations of young parents. In fact, when we come to very great men, no one of them is produced by average, or normal breeding extending over three generations. They come only from progenitors averaging older than the average age for parents. In this connection I want to call attention to the fact that I had a substantial money offer standing three years for the production of a single contrary case. The offer was widely advertised, and many persons tried to find that contrary case, but none succeeded.

In matters of this kind it is well to look at other sources of information as a check to prevent some unconscious mental twist from leading a person into erroneous conclusions. One of these other sources which I examined for this purpose is the milk-producing power of cows. The organs employed in the production of milk are, in many respects, analogous to the brain of man. What is true of one is largely true of the other. If we find by investigation that milk-producing power in cows is evolved in the same way that brain power is evolved in man, then we have a check on our first investigation.

I tested this matter in Holstein-Friesian cows. In those animals a cow produces more milk when she has her second calf than when she has her first one, still more when she has her third calf, more yet when she has her fourth calf, and so on up to some unknown point. This may be seen by a short table taken from official tests, in which table cows of the same age are grouped together.

HOLSTEIN-FRIESIAN MILK PRODUCTION.
Seven-day Official Tests. 1913.

Average Age.	Pounds of Milk.
2 years and 2 months	322.7
3 years and 2 months	400.3
4 years and 2 months	446.8
Over 5 years (av. 7 years)	473.8

Going back to an earlier date when the average milk production was somewhat less than in 1913, I traced the same cows through successive years of lactation to see to what extent continued exercise brought about continued development of power. The result is shown in the following table.

HOLSTEIN-FRIESIAN MILK PRODUCTION.
Seven-day Official Tests. 1904-6.

Average Age.	Pounds of Milk
6 years and 6 months	450.7
7 years and 7 months	472.6
8 years and 3 months	499.8
9 years and 7 months	564.8
10 years and 7 months	563.7

Not every cow in this table increased in milk production every year, but the table itself shows that the increases largely exceeded the decreases. It includes every cow over five, and under eleven years of age recorded as tested in successive years at the dates given. One cow, not in the table, produced 33 per cent. more milk at twelve years of age than at ten and a half.

If a cow produces 400 pounds of milk in a week the question of whether she is a large milk producer, or a small one, is determined by how old she is at the time. If she is a two-year-old, that 400 pounds means that she is a large milk producer, but if she is more than four years old, 400 pounds is a small production.

In testing this matter I made a scale ranging

from 333.2 pounds of milk in seven days for a two-year-old, to 557.4 pounds for a five-year-old. From cows born after Jan. 1, 1901, and tested up to Feb. 15, 1907, I picked only those cows whose milk production for their ages exceeded the high figures in this scale. I could find only 137 of them. By a slight relaxation of this rigid rule I raised the number to 144 cows, and the pedigrees of these cows written out for three generations gave me 1000 female ancestors in these pedigrees. The ages of these females as they appeared in these pedigrees were calculated, and that calculation was compared with a carefully determined average for what is normal. The result showed that the 1000 dams found in these 144 pedigrees averaged nearly 33 per cent. older than what was normal for the breed. In other words, each and every one of these 144 large milk-producers came from successive generations of old dams. Not one came from successive generations of young dams.

The results of this investigation appeared in five articles published from April to June, 1907, in the *Holstein-Friesian Register*. In the first of these articles I stated that any test of this matter must be based on total milk produced, and not on some variable fraction of it as butter fat. And I explained the reason for this in detail. In the last of the five articles I gave examples of how a test directed to butter instead of to milk gave misleading information.

In Vol. 6 of the American Breeders Annual (page 310), F. S. Putney of Columbia, Mo., gives an account of some investigations he made into the pedigrees of Jersey cows at the Missouri Agricultural College. He refers to and quotes from my articles, which shows that he was familiar with them. He says that his work was done "with a view of testing" my "theory." As Putney's investigation has been cited frequently as contradicting what I have presented, we will take a look at his work.

Putney uses Jerseys, but he does not tell us how much milk a two-year-old Jersey is supposed to produce in a week, or month, or year. Neither does he tell us the amount of milk which should be produced by cows of any other age. Neither does he classify his cows in relation to age and production, but lumps them all together. And what is still more, he does not direct his investigation to milk production at all. He directs it to the production of butter, and he does so with full knowledge of my statement, explanation and illustration of the fact that the matter cannot be tested in that way.

There is another angle to this matter. Through the *Journal of Heredity* I offered $1,000 if anyone could show a single case of improvement coming in any other way than in accordance with what I had set forth for men, horses, dogs, and cows. In writing to the editor on Jan. 11, 1916, I said: "If cows are used, the basis must be milk and not butter."—See Dynamic Evolution. In the February issue following the editor says that Putney's investigation was "undertaken for the purpose of testing Mr. Redfield's theory of heredity."

It should be evident that Putney's work had no such purpose, and that the editor knew that fact when he made his statement. As a test of what I presented, Putney's investigation is nothing but a fake palmed off on the public as being the thing which it is not. I have no objection to Putney, or anyone else, making that kind of an investigation if it pleases him and he can give any good reason for doing it, but I object to it being used to deceive the public.

That $1,000 offer was widely advertised and stood for more than a year. That herd of Jerseys at the Missouri Agricultural College is a large one, and Putney tells us that complete milk records have been kept for every cow since 1892. They know at that college where they have got improvements, and where they have not. If they ever got any improvement in milk production in that herd in any other way than in that which I set forth, they should have brought that case forward and claimed that $1,000. It is significant that they did not.

The thing which the reader should particularly get into his mind is the fact that animal powers are developed by exercising them, and not in any other way, and that as long as there is a high degree of activity, powers will continue to develop up to the last years of life. I have given tables which show what occurs with Holstein-Friesian cows under seven-day tests. As corroboration, observe what is found by year tests of 1,497 Jersey cows.

JERSEY COW MILK PRODUCTION.
Year Records—Official Tests—1916.

Ages at Calving.	Pounds of Milk.
Under 2 years	6242.2
2 years to 3 years	6710.0
3 years to 4 years	7317.1
4 years to 5 years	8040.2
5 years to 6 years	8255.0
6 years to 7 years	8340.2
7 years to 8 years	8702.2
8 years to 9 years	8667.0
9 years to 10 years	8643.3
Over 10 years	8900.0

Observe that the oldest cows produce the largest quantities of milk, and that, except for a small irregularity beginning at seven years of age, the increase is quite uniform from beginning to end. The object here, however, is not to to show what occurs under miscellaneous conditions, but to show that continued exercise brings about continued development of the powers exercised. Ordinarily cows are kept in active milk production, but not always. Sometimes they go farrow, or are dried up early for some cause or other.

The largest quantities of milk are produced by old cows, but such cows do not produce the largest quantities simply because they are old. They produce large quantities because they have developed their powers continually for many years.

These tables for the cows show definitely and positively that milk-producing power may continue to develop in the cow up to the later years of her life. We do not have similar tables for the continuous development of mental power in man, but we know a few facts which will enable us to see the same thing here. It requires mental power for a man to carry knowledge in his memory. When a man is thirty years of age he carries more things in his memory than he did at twenty. When he is forty he can carry more than he could at thirty. When he is fifty he can carry still more, and so on up to the last of life.

The next important thing for the reader to get into his mind is the fact that the offspring inherits the power development which exists in the parent at the time of reproducing, and not the power development which existed at some earlier date, or will

exist at some later time. For milk production in cows and brain power in man we may make a direct comparison between the age of the parent and inherited quality in the offspring, because normally power development continues from year to year.

But for trotting power in horses the matter is not quite so simple, because many breeding animals are idle animals. An idle animal loses power by idleness instead of gaining it by exercise, hence, in studying inheritance in horses we must investigate the individual activity of each individual horse. But when we do that we find the same story. The offspring inherits the power characteristics existing in the parents at the time of reproducing.

525 Monadnock Block.

A METHOD FOR USING DAKIN'S SOLUTION FOR CONTINUOUSLY IRRIGATING THE MASTOID WOUND.

By ALFRED KAHN, M.D.,

NEW YORK.

The following is a description of the technique employed by me in irrigation of the mastoid wound with the Dakin solution.

At the time of the mastoid operation the wound is entirely closed except at the upper and lower angles. A rubber drainage tube is inserted and retained in these angles. The drainage tube at the top is left rather long so that it can be easily connected or disconnected at will with the tube leading down from the siphon tube which will be mentioned later. The tube at the lower angle is comparatively short, as it is only intended to keep the most dependent portion of the cavity open for drainage. The wound is not packed with gauze, but is left open so that the fluid can flow in and touch every part of the wound cavity. If it is thought wise, the operator may also place another tube in the external auditory canal. The wound is then covered with gauze and the usual mastoid bandage applied. The tube at the upper angle is allowed to extend out a short distance beyond the bandage. When the solution is not flowing this tube can be disconnected and clamped off from the siphon tube. The arrangement of these tubes at the upper and lower angle

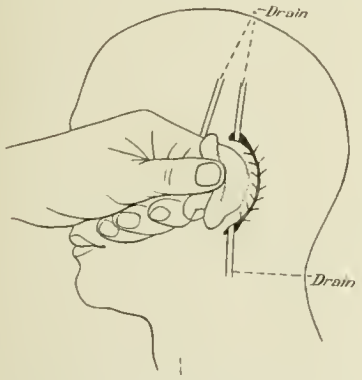

Fig. 1.—Wound closed with tubes inserted into the angles.

of the wound and the closure of the wound is illustrated in Fig. 1.

The patient is then put to bed, and when it is desired to allow the solution to flow the tube at the upper angle is connected with the siphon tube of the syringe. The fluid then flows from syringe to siphon tube and upper drainage tube through the mastoid cavity and out at the lower angle of the wound. The patient is placed so that the mastoid wound will be downward. The head is supported

Fig. 2.—Ring pad with gutter for carrying away the drip.

on an air-cushion pad, not unlike the Kelly pad used in gynecology, but very much smaller. The pad should not be so large that the patient's head will burrow into the gutter of the pad, but only of sufficient circumference so that the opening will surround the bandaged ear. This detail is illustrated in Fig. 2. When the patient is in bed his head rests in the pad and the fluid drips from the mastoid bandage into the pad and is carried off into a waste vessel under the side of the bed.

When the patient is sufficiently well to sit up or be out of bed the following method is adopted. A pad, Fig. 3, is then made a part of the dressing. This pad, Fig. 3, is of rubber, the lower portion shaped like a funnel, its object being to drain the fluid as it passes down from the mastoid wound into the funnel. This pad is firmly attached under the ear and to the side of the head by gauze bandaging placed around it at various points as shown in the illustration. The upper half of this pad covers over the mastoid bandage and aids in directing the solution into the funnel portion of the pad, from which it flows out. Fig. 3 shows the pad firmly attached to the ear and side

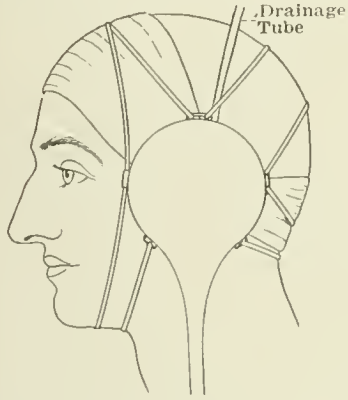

Fig. 3.—Pad for maintaining the dressings in place.

of the head with pad closed. The solution now flows from the syringe, following the same pathway as in the recumbent position, except that the bed pad is replaced by the pad herein described.

50 East Forty-second Street.

THE CLIMATIC ILLUSION IN THE TREATMENT OF TUBERCULOSIS.

By HOWARD CRUTCHER, M.D.,
TULAROSA, NEW MEXICO.

NAPOLEON is credited with saying that "imagination rules the world," and it must be admitted that much evidence may be adduced in support of the statement of the great soldier. Emotionalism has played so large a part in the affairs of mankind that one may well wonder how the light of scientific teaching ever made headway against it. After centuries of bitter experience man learned that he was merely a part of Nature, not superior to its laws and principles, and the fact became clear to him that he must conform his ways to fixed principles and not depend upon miraculous interference in his behalf. Tuberculosis, typhoid fever, and malaria, once looked upon as dispensations of Providence, are now known to appear as the result of natural causes, and their eradication must fall strictly within the scope of applied science. Such absurdities as "cures" and "specifics" are no longer permitted to befog the pathway of the scientific worker in search of rational measures of relief from the ravages of disease.

It may sound wholly incredible, but it is the literal truth that a generation ago draughts of air were regarded as being a fruitful cause of tuberculosis. A frail girl of twenty years, nervous, anemic, and dyspeptic, was suspected by the family physician of "being threatened with weak lungs," a very familiar phrase in those times, and she was forthwith confined within the narrow limits of a stuffy bedroom, where no murderous draughts could reach her, fed sparingly upon dainties, and warned that the slightest exposure to fresh air would be as fatal as a deadly poison.

Medicine, as that term was generally employed, was expected to work wonders, and as often as expected as often failed. A nauseous mixture of fish oil and whisky was depended upon to supply the deficiency in fresh air. A repulsive compound denominated an expectorant was expected to prevent the waste of physical energy from coughing. Dainties of one kind and another were trusted to take the place of wholesome food. My preceptor, a man of no ordinary practical wisdom at the bedside, said one day with mournful resignation, "Cancer and consumption spring from a common cause, the real nature of which we know nothing as yet. Iron and quinine are recommended for consumption, but you may as well give beefsteak and ice cream. No remedy does any lasting good. Our future knowledge of these diseases must come through the microscope. Gross shook his head over cancer as much as Trousseau did over consumption."

Light came, however, not so much from the use of the microscope as from the teachings of practical experience. The story as I first heard it ran somewhat in this style: A young man living somewhere in the East was detected in some financial irregularity and as a punishment was sentenced to a prison term. The prison physician upon examination detected a true case of "weak lungs." The Governor of the State upon appeal granted the offender a pardon and advised him to return to his home and "die under the care of his mother." Instead of doing this, the young man broke his word, journed into the deep pine woods of northern Wisconsin and under an assumed name began life anew as a woodchopper. As his strength returned, his riches grew, until he was abundantly able to return to his Eastern home, repay all old obligations, and settle down as a valued and honored member of the community.

This story, charming as it was, might have lost something of its practical bearing had not another wayward young man under like conditions journeyed to Kansas, where there were no pine woods, and regained abounding health by farm work and stock raising. He, too, returned to the East, where his presence aroused mingled feelings of amazement and admiration among his old-time associates.

These instances, not encumbered with names, places, or dates, of course, were circulated some years before the epoch-making labors of the lamented Trudeau in northern New York began to attract serious attention through his reports to the MEDICAL RECORD. At last, through some fortunate means, the fact became generally acknowledged that innumerable people in all the walks of life, in every region of the country, from the pineries of the Adirondacks to the sterile deserts of Arizona, had resisted the infection or had recovered from its milder manifestations in the earlier stages by breathing pure air, eating wholesome food, cultivating proper bodily habits, and observing generally the teachings of clean living.

It must not be inferred that the writer would approve of any "wholesale" methods of treating tuberculosis or any other disease; on the contrary, no disease demands keener individualization or more unremitting care on the part of the physician than tuberculosis. Meat, eggs, and milk can not invariably be depended upon by any means. Some patients thrive surprisingly well on a dietary largely vegetarian in character. A few well-selected medicines are of the highest value at times. So far as the cough is concerned, it is the same under similar conditions in all climates. Here again the physician must exercise discretion based upon individual experience, one sufferer improving upon cold, dry air, whereas another will do better in a region of more heat and moisture.

As to a change of climate, that also must be determined by cautious individual analysis. That any particular region or climate is better suited than any other region or climate to a preponderance of the human family on account of any pathological condition is the utmost folly. For a person in settled business in the East to break up all ties and fly to some desolate, ill-kept boarding house located in some far away desert, under the pathetic illusion that isolation is a panacea for disease is such pitiable nonsense that the wonder is that any rational being should be guilty of it. In countless instances the ability to earn bread is fully as important as the power to digest it. Those dependent upon their labor from day to day for the means of living must not suppose that the impossible can be accomplished more readily in one region of country than in another. Nor must unbounded confidence be placed in the highly colored and too-frequently misleading reports that emanate from purely interested sources. The most preposterous

absurdities are frequently sent forth by honest but misguided persons who mistake illusions for realities. Many things pleasing to the eye and profitable to the mind bear no relation whatever to the cure of disease. A charming landscape is no substitute for wholesome food, comfortable surroundings, and skilled medical supervision. There is no more a specific for tuberculosis than there is for poverty and old age; and so far as climate alone is concerned it has no more curative effect in this condition than it has in gallstones or cancer.

Medicolegal Notes.

Where Sunstroke Held an Accident.—An accident insurance policy against bodily injury sustained through accidental means and resulting directly and exclusively of other causes in immediate continuous and total disability included sunstroke suffered through accidental means. The holder, when riding on a street car to his work, suffered a sunstroke when about to alight. It was held that he was injured by "accidental means." The court said: "The contention of appellee [the insurance company] is that in the term 'accidental means' as therein used some violence, casualty, or vis major is necessarily involved, and that disability or death engendered by exposure to the sun's heat, or other atmospheric influences, cannot properly be said to be accidental, unless the exposure is itself brought about by circumstances which give it the character of an accident. In other words, if the exposure to the heat of the sun was intentionally encountered in the ordinary performance of a person's usual duties of life or occupation, it is not accidental; but if a person should by reason of shipwreck or other like occurrence, be left in a position in the heat of the sun, and thereby suffered sunstroke, the means would be accidental. This is the view taken in the case of Sinclair v. Maritime, etc., Co., 3 Ell. & Ell. 478, and that case is followed to a great extent by the following cases: Dozier v. Fidelity, etc., Co. (C.C.), 46 Fed. 446, 13 L.R.A. 114; Semancik v. Continental Casualty Co. (1914) 56 Pa. Super. Ct. 392; Continental Casualty Co. v. Pittman (1916) 145 Ga. 641, 89 S.E. 716; and Bryant v. Continental Casualty Co. (Tex. Civ. App.) 145 S.W. 636. * * * We are of opinion that the better reasoning points out, and the weight of authority holds the true test to be, that if in the act which precedes the injury, though an intentional act, something unusual, unforeseen, and unexpected occurs, which produces the injury, it is accidental; but, if in the act which precedes the injury something usual, foreseen and expected occurs, which produces the injury, it is not accidentally effected. We are supported in our holding by the following cases, which involve the question of whether sunstroke suffered, while engaged in the usual daily duties, is accidental: Continental Casualty Co. v. Johnson, 74 Kan. 129, 85 Pac. 545, 6 L.R.A. (U. S.) 609, 118 Am. St. Rep. 308, 10 Am. Cas. 851; Pack v. Prudential Cas. Co. (1916) 170 Ky. 47, 185 S.W. 496, L.R.A. 1916 E 952; Higgins v. Midland Cas. Co. (1917) 281 Ill. 431, 118 N.E. 11; Bryant v. Continental Casualty Co. (1916) 107 Tex. 582, 182 S.W. 673, L.R.A. 1916 E 945, Am. Cas. 1918 A 517. The last case above cited overrules the holding of the lower court in the same case reported in 145 S.W. 636, upon which the Pittman and Semancik cases, supra, were largely based."—Elsey v. Fidelity & Casualty Co., Indiana Supreme Court, 120 N.E. 42.

Accident Insurance—Presumption Against Suicide.—Strictly speaking, a means is accidental only when dissociated from any human agency, but this narrow interpretation is not recognized in the law of accident insurance. Any event taking place without the foresight or expectation of the person affected is here considered accidental, even though the accident would not have happened but for his voluntary act. In an action on a policy of accident insurance for death caused by drinking carbolic acid, the petition averred death from "accidental carbolic acid or toxic poisoning." This the answer denied and averred "suicide by the intentional drinking of a deadly poison, namely, by the drinking of carbolic acid." The reply contained a denial and admission of death from "drinking a deadly poison, to wit, carbolic acid." It was held that the burden was upon the plaintiff to produce evidence showing that the death was accidental and not suicidal. The presumption against death by suicide is prima facie only and rebuttable. It prevails when the cause of death is unknown. It does not prevail as a presumption in the presence of facts bearing upon the question whether death is intentional or accidental. When evidence is adduced which is contrary to such presumption, or the presumption is met by conflicting presumptions, it disappears, although the fact upon which it rests may still remain proper to be considered in arriving at a conclusion.

There is the almost conclusive presumption that when one drinks he knows what he is drinking, especially so if he is drinking carbolic acid; the presumption that when one drinks carbolic acid he knows the poisonous character of the liquid; and the presumption that one intends the natural consequences of his own act. These presumptions bear upon the question of intent, and the force of the original presumption must be lessened by the force given to them. While it may well be urged that we are still uncertain as to the actual intent, the presumption against intentional death can no longer prevail as prima facie proof. Judgment for the plaintiff was reversed.—Grosvenor v. Fidelity & Casualty Co., Nebraska Supreme Court, 168 N.W. 596.

The Use of Saccharin.—Reversing a conviction for the alleged adulteration of strawberry soda with saccharin, the New York Appellate Division holds that the use of one one-hundredth of 1 per cent. of saccharin in bottled strawberry soda labeled "Sweetened with sugar and one one-hundredth of 1 per cent. of saccharin (benzo-sulphinide)" comes within the proviso of Sanitary Code of City of New York, Section 68, relating to a mixture of compounds known by their own distinctive name. Since saccharin is not injurious to health, the court holds its use in food products may be regulated, but cannot be prohibited, under the exercise of the police power.

The court said, in part: "The uncontroverted evidence shows that the use of soda water as a beverage containing this quantity of saccharin could not possibly be injurious to health, and that there is greater danger of injury to health from consuming too much sugar than from the consumption of saccharin in such a percentage. It also appears that the use of sugar in any form is injurious to people suffering from diabetes and some other diseases, while the use of saccharin by them to flavor food and render it palatable is prescribed by medical authorities.

"The only possible theory on which such use of saccharin could be prohibited is to prevent deception, by leading purchasers and consumers to think that the food products had been sweetened by sugar, which contains a food value, and not by saccharin, which has no food value. There is no evidence of deception, and the label is designed to prevent deception. Soda water is not a natural food product, but is a compound of food products, and I am of opinion that such use of saccharin comes within the proviso contained in said section 68 of the Sanitary Code relating to a mixture of compounds known by their own distinctive name, and that the label complied with the requirements thereof * * *

"If a standard of purity with respect to the ingredients to be used in making soda water had been prescribed by the Legislature, or by legislative authority, then it might well be argued that no other ingredients could lawfully be used in making it. See dissenting opinion of Leonard, P. J., in People v. Cipperly, 37 Han, 324, on which the decision was reversed, 101 N. Y. 634, 4 N. E. 107. It is perfectly obvious that, entirely aside from the question of disease or medical advice, some people may desire, especially in hot weather, a cooling beverage that contains no food value, or that has been sweetened to render it palatable by the use of saccharin, instead of by the use of sugar, and there is, therefore, no occasion or authority for prohibiting such use of saccharin." People v. Excelsior Bottling Works, 171 N. Y., Supp. 733.

Military Medicine.

Surgery of the Chest as Carried Out at the Front.—Perhaps no branch of surgery has been more greatly revolutionized during the war than the methods of dealing with injuries of the chest. The change has been simply that of harmonizing of adapting the principles of surgery as they are now applied to other wounds to those of the lung and chest.

As Colonel William Taylor, A. M. S., Consulting Surgeon to the Forces in Ireland, points out in a review of the surgery of the chest as carried out at the Front, published in the *Dublin Journal of Medical Science*, November, 1918, this change has been the outcome of the work of Duval and many other surgeons, British, French and American. It was estimated that the mortality due to chest wounds at the aid posts was from 25 to 30 per cent. The seriously wounded die either on the field or at the aid post. Hemorrhage and mechanical asphyxia, open thorax with traumatic dyspnea are the two chief causes of death. Deaths on the field are mainly due to hemorrhage from the large vessels. Cases of that type do not appear in any statistics. The mortality of chest wounds at the casualty clearing stations averaged from 18 to 20 per cent. In stationary or base hospitals the mortality was about 10 to 12 per cent. The mortality is thus proportionately lower the further one proceeds from the fighting line. The cases which reached the base hospitals were those in very good condition who had survived the complications of the first few days. The mortality of these cases at the three different places at which they might be treated averaged from 18 to 20 per cent. That did not include the mortality arising from chronic sequelæ, such as long-standing empyema, abscess of the lung and late complications generally. Such a mortality was unsuspected before the war.

According to Taylor the explanation is simply that experience before the war was based upon the practice of bullet wounds, whereas in this war shell wounds have preponderated. In Duval's experience, the proportion of shell wounds to bullet wounds was as 3 to 1, whereas the mortality of shell wounds to bullet wounds was 14 to 1. A bullet wound is either fatal at once, from hemorrhage due to injury of a large vessel, or it is comparatively benign. A bullet wound is either aseptic or seldom followed by grave infection, and to this is due its lower mortality. It is the danger of sepsis in connection with shell wounds that renders them so serious.

A shell wound in which a foreign body is retained in the lung is attended by a much higher death rate than a through and through shell wound. Duval was the first to state positively that immediate operation could save some of the cases of severe pulmonary hemorrhage. Hartmann, who was at first strongely opposed to operation for the arrest of pulmonary hemorrage, became strongly in favor of it. Tuffier followed suit. All cases of severe chest wounds are in a condition of grave shock, and one must judge quickly whether the dangerous condition is due solely to shock or to hemorrhage. If there is an open thorax, or if the blood is flowing freely from a small entrance or exit wound, there is no difficulty in determining the question. It is in cases of intrapleural hemorrhage that one is in doubt as to how to act. Blood pressure alone is of use in determining the question. If, in spite of warmth, the blood pressure progressively falls, operation is indicated, as hemorrhage is outweighing shock. It has been shown that thoracotomy has practically no effect on arterial pressure. The operation can be performed with a very low blood pressure, when a laparotomy could certainly not be tolerated. In short, the patient's general condition never offers a contraindication to thoracotomy. It is believed that two-thirds of the cases of chest wounds with hemorrhage can be saved by early operation and direct arrest of bleeding from the lung. Infection of the hemothorax in bullet wounds is exceptional. Colonel Elliott, F. R. S., has demonstrated that the infection of the hemothorax originates in the clots of fibrin and blood which form on the surface of the wound, and collect in the pleural cavity.

The treatment of penetrating wounds of the lung will depend upon whether the wound of the lung is entirely superficial, whether the foreign body is retained, or whether the case is one of the through and through types. (1) For a superficial wound of the lung, excision may be practised, and the wound sutured, so as to arrest hemorrhage. (2) In penetrating wounds with retained foreign body, the foreign body should be extracted through its entrance tract. Fragments of clothing should be removed. The tract should be then cleansed, and the opening into the lung sutured, so as to guard against subsequent infection of the pleura from the lung. (3) In penetrating through and through wounds, suture of the entrance and exit wounds must be performed, but Duval has never carried out the ideal procedure of cleansing out the entire tract. Sepsis in the lung occurs early, much earlier than in the pleura, hence early operation is advisable. Bullet wounds may be left alone unless they give rise to dangerous hemorrhage. Minute fragments of shell may also be left alone, as they do not carry in pieces of clothing, and they are often sterile. "Open thorax" is a term coined to describe those cases in which the thoracic wall is widely opened and air passes directly into the pleural cavity with each respiratory movement. For two reasons such a wound must be closed: to lessen the danger of asphyxia, and to protect the pleura against infection from without.

Wounds of the diaphragm must always be sutured. If hemorrhage is taking place it must be dealt with first; otherwise a wound of the diaphragm should always be treated first. If the liver is involved the opening is, if necessary, enlarged, so as to give access to that organ. The liver wound is then cleaned with a Volkmann's spoon, followed by swabbing, and sutured. It is strongly emphasized that a foreign body should never be left in the liver. The opening in the diaphragm is then closed, with one or more mattress sutures, and the chest is subsequently treated. Duval delivers the lung on to the chest wall, almost in the same way as the small intestine from the abdomen. He has proved that the rules of general surgical technique are perfectly applicable to the lung. Drainage of the pleura need never be considered. It is not required, and is not practised. When the thorax is

opened, the lung should be dealt with first, and the toilet of the pleura performed subsequently.

Taylor states that there are three methods to arrest hemorrhage from the lung. (1) Plugging, which is only a makeshift, but which under certain conditions must be resorted to. (2) Suture of the lung. (3) Ligature of the bleeding vessel, which is ideal. Practice has shown that one can count upon the resistance of the lung tissue itself to arrest hemorrhage in a tract, both ends of which have been closed.

With regard to the extraction of foreign bodies, it is generally stated that it is best not to make a new incision, but to make every effort to extract the foreign body through the opening by which it entered. The tract is subsequently cleaned out with a gauze wick held in a long forceps. Suturing should be accurately performed, and the pleura carefully adjusted. The pleural cavity must be emptied of blood and clot, and the whole extent of the pleural cavity wiped dry. The opening in the chest wall is then closed by careful suturing in layers. The air may or may not subsequently be withdrawn. Distress in breathing is often completely relieved by its withdrawal. If a septic effusion develops later it can be drained.

Massage and Electrotherapeutic Work in a War Hospital.—It has been demonstrated in all the orthopedic hospitals of Great Britain that the employment of massage and electrotherapy is an essential part of treatment for the relief and cure of pain and joint stiffness subsequent to injuries by wounds, or for medical conditions. To Sir Robert Jones is due not only the realization of this truth but also the carrying out of a scheme to place such treatment within the reach of all wounded soldiers. As is well known, through the Liverpool orthopedic surgeon's initiative, a chain of orthopedic hospitals has been established throughout Great Britain provided with all the means for employing massage and electrotherapy to the best advantage. While the details of treatment are familiar to members of the medical profession no attempt appears to have been made to indicate the results of treatment. In the *Practitioner* for December, 1918, Capt. N. Morris, R. A. M. C., has endeavored to supply to some extent the hiatus and has contributed a paper based upon the results of about 1200 cases treated in the Lord Derby War Hospital, Warrington, England, during the past nine months.

The majority of the cases treated were surgical, and by far the larger number of these consisted of injuries in which movements of joints were involved to a greater or lesser extent. Morris calls attention to the need for the early treatment by massage of wounds which do not directly involve joints. Scarring in the tissues, with the formation of large bloodless cicatrices pressing on the surrounding muscle substance subsequent to flesh wounds, is frequently responsible for pains and stiffness of the joints. Of course, the danger of spreading septic material into the neighboring tissues is a risk which must be considered in early treatment, but Morris thinks that in cases in which sepsis is not very extensive, if the massage is gently done, this may be neglected, while the tonic influence may go a long way to ensure speedier healing. The one contraindication is when the massage causes the patient discomfort. However, whatever opinions may be held on septic cases, there can be no question that once the granulations are healthy, massage ought to be started immediately. The author goes so far as to suggest, while acknowledging that the idea is somewhat Utopian, that each ward of a general hospital should have attached to the staff a masseuse, who could give massage and faradism. Of the various forms of treatment massage is the most valuable, mainly because of its simple nature. Passive movements are very important and the indication for the duration and extent of the movements is the pain felt by the patient. Radiant heat has been found very useful in lessening the pain of joint injuries, and as a preliminary to forcible movement under an anesthetic. It appears, to some extent, to get rid of the induration of the tissues, and is thus a very useful adjunct in all cases of that nature.

Faradism is very important in joint and nerve injuries, especially in the latter. Morris is of the opinion that although ionic medication is of some value, its value has been rather overestimated. In some cases of chronic rheumatism so-called ionization with a 2 per cent solution of potassium iodide seems to have a temporary beneficial effect. Also ionic medication appears to be of considerable value in loosening tight cicatrices and in the freeing of nerves, provided the treatment is begun early enough. One class of cases in which ionization is of little or no value is that in which there has been involvement of bone with consequent formation of callus.

Each patient ordered massage and electrotherapeutic measures was examined before beginning treatment and all defects of movement and sensation, subjective and objective, were noted. If there were any signs of nervous involvement, the electrical reactions of the muscles suspected of being implicated were tested. During the period of treatment, notes of the progress of the case were taken weekly as far as possible, and the condition of the patient on discharge was noted.

The results on the whole were satisfactory, depending of course, to a large extent, on the character of the injury. With regard to the use of splints the author points out that the full return of mobility was in many instances greatly retarded by the prolonged use of slings and splints. This cannot be deprecated too much, for the tendency of joints to stiffen is very great when kept fixed. If splints are necessary for any length of time, it is essential that massage and some slight passive movements should be given daily, if at all possible.

Nine patients in the Lord Derby War Hospital, who had injuries to the hand, suffered from causalgia which was relieved more or less by stabile faradism or ionic medication with potassium iodide. Seven patients on whom bone plating had been performed were treated by massage, and it is interesting to note that in five on whom massage had been begun soon after the operation good union was the result, while in the other two, massage having been postponed for some reason, the union was delayed and the limb was much weaker. Twenty patients were treated for trench feet, twelve of whom were more or less completely cured, and six were greatly relieved.

One Million Persons Killed by Lice.—Lieutenant Lloyd, chief entomologist in northern Rhodesia, in a recent publication declares that of the insects responsible for the death or disablement of hundreds of thousands in the war zone, the louse was the most deadly, and is accountable for at least one million deaths. This is said to be but a rough estimate, the probability being that the toll is much larger, for in Serbia alone typhus infected nearly one million persons, killing 500 a day in the little city of Jassy alone, while 200 of the 1,200 medical officers in the country died of the disease, which spread over Russia, Austria, Germany, and the Balkans generally. Many thousands of cases of relapsing fever and trench fever were also caused by the louse. This report, in discussing the typhus outbreak at the Wittenberg Camp in Germany, from which the German doctors fled, makes the statement: "The Germans knew, as we do, that typhus is spread by lice, and that the epidemic could have been cut short and stamped out a week after its commencement by the disinfection of all prisoners." But disinfection was not attempted, and the doctors fled. A Russian prisoner of war who recently returned to Russia, asserted that when typhus struck the Russian prison camps in Germany his comrades died at the rate of 500 a day and were buried three deep in a grave. It is reported that 750,000 died in prison.

Care of Wounded on Stranded Transport.—The American troop transport, *Northern Pacific*, which ran ashore off Fire Island on January 1, had aboard 1,671 men and 73 officers who were sick or wounded. Col. J. M. Kennedy, surgeon of the Port of Embarkation, despatched Lieut.-Col. F. J. Pierce of the Medical Corps with 220 officers and enlisted men by special train to Bay Shore to care for the patients as soon as they could be landed. The litter cases were sent to Debarkation Hospital No. 3, in the old Greenhut store, the mental cases to the Messiah Home in the Bronx, the contagious cases to Secaucus, N. J., while the less serious cases were distributed among the other military hospitals in the vicinity. The local Red Cross fed the troops as soon as they were landed, and the Woman's Motor Corps had six ambulances at hand to aid in the transfer of patients to the train.

Enlist Nurses in Public Health Service.—The Council of National Defense will muster out its nursing committees this week, after having completed the work of recruiting nurses for war service. The National Organization for Public Health Service, with headquarters in New York City, will help recruit nurses into peace service. To encourage the nurses who will leave war work to undertake civic duties, the National Organization of Public Health Nursing is planning to establish short courses in public health work to which army nurses will be eligible. In addition, the organization hopes to raise a scholarship fund to pay the expenses of the nurses during training. The value of the service rendered by the public health nurse has so impressed government officials that such men as Secretary Baker, Secretary Wilson, and Surgeon General Rupert Blue of the Public Health Service have issued an appeal to the National Organization for Public Health Nursing for more nurses to carry out the national reconstruction program.

Army Health Improves.—The Surgeon General's report for the week ended December 27 shows continued improvement in health conditions of troops in the United States. Both influenza and pneumonia cases decreased. The Hoboken port of debarkation was the only station reporting more than 100 new cases of influenza for the week. Eleven new cases of beri-beri were reported from Camp Las Casas, Porto Rico.

Major Victor C. Pedersen has received honorable discharge from the Medical Corps of the U. S. Army and will resume practice in this city.

Deaths in the Service.—LIEUT. JOSIAH A. POWLESS, M. C., U. S. Army, of Oneida, Wis., a graduate of the Milwaukee Medical College, in 1904, on duty with the so-called Lost Battalion of the Three Hundred and Eighth Infantry, Seventy-seventh Division, died on November 6 as the result of a shrapnel wound of the lung received in battle in the Argonne Forest on October 14, aged 46 years. He was an Oneida Indian and a graduate of the Indian school at Carlyle, Pa.

LIEUT. EDWARD GLENN HENRY, M. C., U. S. Army, of Oil City, Pa., a graduate of the University of Pennsylvania, in 1911, aged 29 years, died in American Red Cross Military Hospital No. 4, Mossley Hill, Liverpool, England, on November 7, from pneumonia.

LIEUT. JOHN WALTER RENNER, M. C., U. S. Army, of Hilliards, Ohio, a graduate of the Ohio State University, in 1912, aged 28 years, is reported to have been killed in action in Flanders on November 4.

LIEUT. DIETRICH LUDWIG BARTLING, M. C., U. S. Army, of Bloomfield, Neb., a graduate of the Chicago College of Medicine and Surgery, in 1917, died while on duty at Fort Sill, Okla., from pneumonia following influenza, on October 20, aged 31 years.

CAPT. JOHN BUSBY URY, M. C., U. S. Army, of Defiance, Ohio, a graduate of Rush Medical College, in 1903, died at Fort Oglethorpe, Chickamauga Park, Ga., about December 8, from pneumonia following influenza, aged 40 years.

LIEUT. JAMES FRANCIS DORMAN died of influenza at his home in South Manchester, Conn., on December 28.

CAPT. HARVEY LASHER THORPE, M. C., U. S. Army, of Los Angeles, a graduate of Rush Medical College, in 1909, who left for overseas on October 15, died of pneumonia, following influenza, at sea, on November 2, aged 36 years.

LIEUT. JOHN EDWARD WILLIAMS, M. C., U. S. Army, of Roselle Park, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1913, died from paratyphoid fever in Chaumont, France, in August, aged 26 years.

LIEUT. LEECK KEY CRACRAFT, M. C., U. S. Army, of Elm Grove, Wheeling, W. Va., a graduate of the University of Virginia, Charlottesville, in 1905, died from pneumonia, following influenza, at his home, on November 26, aged 36 years.

LIEUT. THOMAS REED FERGUSON, M. C., U. S. Army, of Kirkwood, Pa., a graduate of Jefferson Medical College, in 1906, died from pneumonia, following influenza, in the Lancaster, Pa., General Hospital, on October 2, aged 33 years.

THE ETIOLOGY OF SPRUE.

THE etiology of a very considerable number of the tropical diseases is unknown, and sprue is one of these. Perhaps the latest of the many causes which have been suggested for this profound alimentary disturbance is that it is a streptococcal infection. Sir Leonard Rogers was the first to attribute sprue to this origin. In the *Lancet*, June 6, 1914, he reported the successful treatment of two patients with a vaccine of streptococci which had been isolated from their mouths. Dr. Lucius Nicholls, director of the Bacteriological Institute, Ceylon, writes in the *Indian Medical Gazette*, November, 1918, concerning streptococcal infection as a possible cause of sprue. He wisely draws attention to the fact that streptococci can be isolated from the mouths of the majority of persons in normal health and that consequently any claim that they are the cause of a disease requires considerable substantiation. Moreover, it is very necessary to attempt to define the character of the streptococcus associated with sprue; and this raises the vexed question whether or not the organisms of this class which are found in etiological relationship with so many and various diseases can be described satisfactorily. The results of various morphological, cultural, and serological tests made by Nicholls for the purpose of distinguishing between different types of streptococci were as follows: So far as morphological and cultural tests are concerned, the outcome may be summarized thus: The streptococci isolated from cases of sprue do not possess a capsule, they are nonhemolytic, they are not lyzed by ox bile, they do not produce acid from mannite in the serum water of Hiss, and they produce green colonies on blood agar. Nicholls has tested the sera of sprue patients with the organisms isolated from their mouths, but the results have been so irregular and indefinite that he could form no conclusion in such cases.

With regard to the complement fixation test, he has tested the sera of three patients who showed all the definite clinical symptoms of sprue, and serum from two persons in normal health was used for control. The result was that 0.01 c.c. of the serum of patients suffering from sprue failed to fix the complement, whereas .05 c.c. produced complete fixation. Normal serum showed practically no power of fixing the complement. With streptococcal vaccines Nicholls has treated or has under treatment nine patients, and he is strongly of the opinion from the results thus far that the good results obtained from vaccine by Rogers will be duplicated in the nine cases. It must be borne in mind that pathogenic organisms exhibit virulence and elective affinities for various tissues, and it is known that streptococci are able to acquire or lose these properties.

The author points out that sprue is almost wholly confined to thickly populated countries in which the climate is humid and warm. Further, the majority of the inhabitants of Ceylon are addicted to the habit of chewing, this conduces to the habit of spitting and therefore there is every chance of streptococci being continually passed from one person to another whose mouths have been irritated by chewing. It does not seem, then, unreasonable to suggest that in this manner streptococci may increase in virulence and acquire an elective affinity for the alimentary mucosa.

It has been frequently suggested, of course, that sprue is a disease due to errors of diet. It has been even hinted that it might be placed in the category of what are known as deficiency diseases. In fact, sprue possesses many symptoms in common with pellagra, which is generally regarded as a deficiency disease or as due to errors of diet. Pellagra and sprue somewhat closely resemble each other in many of their manifestations. There is the same wasting of the organs and thinning of the walls of the alimentary tract, and sore mouth and intractable diarrhea. As Nicholls remarks, the suggestion that an error in diet has prepared the way for a streptococcal infection of the alimentary tract will explain many factors associated with sprue, and it may be added with pellagra also.

Some well-known investigators have held the view that scurvy was due to a streptococcal infection, and if the view is correct it may be that the absence of a vitamine from the food renders the system open to an attack by streptococci. Nicholls notes, that according to Rogers (*Indian Medical Gazette*), April, 1918, many military officers have observed when on campaign that the number of cases of scurvy can be reduced to almost a disappearing point by strict attention to mouth cleanliness among the troops. It appears quite within the realms of probability that the so-called deficiency diseases are not directly owing to lack of vitamines, but to the fact that this deficiency of the vitamine element has so reduced the resisting powers of the body that it is susceptible to the attacks of streptococci which are lying in wait in the mouth for such an opportunity. It certainly does seem that sprue has several points in common with pellagra and to a less extent with scurvy. Experiments in this direction should be productive of valuable and interesting results. In the meantime enough is known already of sprue, scurvy, and pellagra to state that in their treatment the indications are to eat suitable food,

that is, food containing the essential vitamine elements and to keep the mouth scrupulously clean. The maintenance, especially, of a clean mouth is a preventive measure against disease, the importance of which is frequently overlooked.

THE CEREBROSPINAL FLUID IN SYPHILIS.

Besides the Wassermann reaction in cases of syphilis it is also of absolute necessity to ascertain if the central nervous system has become infected by the spirocheta, and to what extent it has become involved. When the meninges are involved in the process the organism assumes an offensive attitude in the form of a more or less marked lymphocytosis, and therefore a means of great precision for detecting this resides in an examination of the cerebrospinal fluid. In the normal state the cerebrospinal fluid contains one or two cells (Nageotte's cell) per cubic millimeter, so that if this number is increased infection may be said to exist, and this is all the more pronounced the greater the number of cells present. Thus, in certain instances of general paralysis, tabes, or secondary luetic meningitis, more than one hundred white cells per cubic millimeter will be found. To obtain the requisite amount of cerebrospinal fluid (from two to ten cubic centimeters) spinal puncture should be made between the last lumbar and first sacral vertebræ. Albumin and the globulins should be looked for, and although in no way specific, the presence of the former indicates an involvement of the meninges, while on the other hand an increase in the globulins is distinctly specific.

For the research of the albumins twenty centigrams by weight of pure nitric acid is added to one cubic centimeter of cerebrospinal fluid. The result is read in five minutes, and with a little practise the amount of albumin is readily ascertained. For more precision Bloch's scale may be used. This scale is composed of tincture of benzoin in glycerinated water. Normal cerebrospinal fluid contains twenty centigrams of albumin per liter; thirty to fifty centigrams represent a slight albumin reaction, while from sixty to eighty centigrams represent a strong reaction, such as is found in tabes or general paralysis. The research for the albumins and globulins should be carried out with great precision, and two methods are at our disposal and should be employed together. The first is Nonne's test, which consists in mixing equal parts of cerebrospinal fluid and a saturated solution at 80° C. of ammonium sulphate C. P. The presence of globulins is made evident by a more or less marked turbidity. It is always prudent to use a control tube in which a physiological saline C. P. solution takes the place of the cerebrospinal fluid.

The second method is due to Noguchi. Take from 0.2 to 0.4 c.c. of cerebrospinal fluid and five times its volume of butyric acid C. P. (free from caproic or acetic acid). Boil the mixture lightly and add normal soda in a quantity equivalent to the quantity of liquid. Boil again lightly and then allow it to rest. According to the case, the result can be read in from five minutes to one or two hours. The richness of the globulin content is proportional to the flakiness of the liquid. The use of a control tube is essential.

Wassermann's test is made in the cerebrospinal fluid according to the ordinary procedures, but the liquid must not be heated. It is now known that besides tabes and general paralysis there is almost always a secondary luetic meningitis, and that the reaction of the cerebrospinal fluid will be distinctly influenced by energetic treatment. It happens, although perhaps less frequently than during the primary stage, before the appearance of the roseola, that the meninges may be involved late, so that at the end of treatment, after having obtained a negative blood reaction, the cerebrospinal fluid should also be examined, and one must not be content simply with a Wassermann of the blood.

PRIMARY SUBACUTE TUBERCULOUS PLEUROPERITONITIS.

Among the various manifestations of tuberculosis on the serous membranes, primary subacute tuberculous pleuroperitonitis, first individualized by Fernet, requires a place by itself. It should in particular be distinguished from acute pleuroperitonitis and the forms secondary to a visceral tuberculous lesion in evolution. Thus defined, it is clinically a distinct entity, usually occurring in robust and healthy individuals, but whose antecedents, when carefully gone into, will reveal the influence of many of the predisposing causes of tuberculosis, particularly heredity and alcoholism. The lymphatic origin of the affection maintained by the earlier writers on the subject should now probably give way to the blood theory, which better fits in with recent research work on tuberculous affections of hematogenous origin. Having entered the organism by the respiratory or digestive tract, the bacillus of tuberculosis, after having developed or not a latent lymph-node focus, travels by the circulation and colonizes on the serosa. The reason for this localization as yet escapes us, and only hypotheses can be offered, such as the preference of the tubercle bacillus for certain tissues of common origin or the fragility of the serosa. At all events, this granulosis undergoes its evolution in such a way that it can unquestionably be regarded as an evidence of attenuated infection and resistance of the organism. For that matter, this resistance may be forced, and the tuberculous infection then continues its evolution after this first phase. Although anatomically it is a miliary process, which can be differentiated from similar processes, it offers clinically, from the simple fact of its particular localization, a symptomatic *ensemble* which is always identical and of a distinctly special behavior.

Following upon indefinite prodromes, mild general and digestive disturbances, a slight ephemeral febrile state, an adhesive or ascitic peritonitis su-

pervenes, accompanied by pleural phenomena, with a small amount of fluid in the thorax. After the lapse of a few weeks the physical signs regress and the patient enters upon convalescence. But although the subject may be considered cured of his pleuroperitonitis, the tuberculous infection has not become arrested for all that. It may very well continue to undergo its evolution, and it not infrequently terminates in visceral localizations. Although the evolution may be favorable, a most guarded ultimate prognosis must be made.

The diagnosis of a tuberculous pleuroperitonitis is easy to make in most cases by an attentive examination of the patient, supplemented by laboratory research. After having distinguished acute pleuroperitonitides, polyseritides, and the hepatic cirrhoses, the physician should next establish the primary character of the process by a careful search for possible tuberculous foci undergoing their evolution in the organism. In this way one will be able to distinguish Fernet's syndrome from the secondary types, a matter which is of the greatest interest and importance from the viewpoint of the prognosis.

Incompatibility of Quinine and Aspirin.

Dr. Saenz de Santa Maria y Marron, writing in *El Siglo Medico* for October 12, relates that during a year's experience in the use of aspirin he has learned that the combination with quinine is an undesirable one. In giving remedies in combination we expect synergism in action, a result superior to that obtained by uncombined use. Failure to obtain a heightened effect is itself sufficient to do away with the combination. But in such combinations we may get failure of a higher type—either refusal of one remedy to act or else actual untoward result of some kind. The writer states that his expectation was often defrauded, and cites examples. There was one patient who was getting 25 cgms. of each drug three times daily, and who showed on the following day a severe tachycardia, restlessness, and adynamia. The case was one of influenza, in which, in the author's experience, the heart frequency is by no means unduly great, by reason of some action by the grip toxin on the vagus. The possibility of an idiosyncrasy was dashed by noting analogous behavior in a series of other cases. The problem was taken to the pharmaceutical laboratory, and the evidence appears to show that under the catalytic action of aspirin in the stomach or blood the quinine was changed to a toxic derivative which was termed quinotoxin. This latter, an isomer of quinine, appears to be known to chemists, and it has the reputation of being able to cause death. The brevity and vagueness of the article prevent a complete visualization of the author's notions on the subject, but he is opposed to polypharmacy on the principle that while one remedy may potentize another in some cases, there is also a danger that one remedy can denature another into a toxic substance. The lessons are plain, for every alleged synergistic combination must have this possibility excluded before use on man, and new substances must not be carelessly mixed with old ones.

Freedom from German Chemical Domination.

Among the compensations of the war, not the least has been the impetus given to chemical industries in this and other of the allied countries under the lash of necessity. The German-made stocks of dyes and drugs being exhausted, it was seen to be a question of making them here or going without. Salvarsan and neosalvarsan, novocain, aspirin, salipyrin, veronal, and other drugs have for some time been made here, usually under special names, and recently valerianic acid and the valerates have been added to the list of American-made products. It now rests with the physicians and pharmacists of the United States to prevent the strangling of this new industry by the German manufacturers, who will try to dump their wares here as soon as the war is over, underselling us for a time until our own manufacturers have been forced out of competition. Then the prices will go up, and Germany will again have us in economic thraldom. The time to prevent this is now, and the way to prevent it is to insist upon the use of American-made drugs only.

The New Directory.

The Medical Directory of New York, New Jersey, and Connecticut for 1918 made its appearance in December. The size of the work has been greatly reduced, to its very serious hurt. Among the omissions is that of the list of hospitals and dispensaries, and another most useful feature which has been dropped is the alphabetical list of physicians. These omissions, probably thought necessary because of the high price of print paper, have greatly impaired the value of the Directory; its beauty was spoiled several years ago by the adoption of a stiff paper cover with an incoercible tendency to warp. The new Directory contains the names of 18,481 physicians, of whom 2,723 reside in New Jersey, 1,435 in Connecticut, and 14,323 in New York, 7,921 of the latter being in New York City.

News of the Week.

New Governor Outlines Policy on Public Health Problems.—Governor Alfred E. Smith of New York, in his inaugural address made a number of recommendations in reference to social and public health legislation. He believes that it is of particular importance to the State to secure adequate protection for workers, especially women and children, and recommends the passage of legislation to lift labor out of the category of commodities or articles of commerce. He recommends the establishment of a minimum wage commission of three members which shall have the power to fix the minimum wage to be paid to women and children. Governor Smith would amend the compensation law in keeping with the constitutional provision, to the end that occupational diseases and injuries may be subject to its provisions. He strongly urges the enactment of a health insurance law which he believes will not only protect the wage earner in case of sickness but will also result in greater precautions being taken to prevent illness and disease and to eliminate the consequent waste to the State therefrom. Proper provision,

he says, should be made for maternity insurance on the interest of posterity and of the race.

Advocates Serum for Influenza.—Dr. Eugene R. Kelley, Commissioner of Health of the State of Massachusetts, has recommended to Governor Coolidge an additional appropriation of $5,000 for the instruction of physicians in the treatment of influenza and bronchopneumonia cases with the blood serum of persons who have had the disease. A commission appointed by Dr. Kelley to investigate the blood serum treatment report that at the Naval Hospital in Chelsea the mortality in influenza and pneumonia was markedly lowered after the introduction of the serum treatment. Dr. Kelley plans to have a number of physicians instructed in the use of the serum at the Naval Hospital and later to demonstrate the method in hospitals throughout the State.

Juvenile Crime Increases.—In her annual report as chief of the Children's Bureau, Miss Julia Lathrop states that more than 6,500,000 children have been weighed and graded in the Bureau's Children's Year Campaign to save at least 100,000 infant lives. The report shows that juvenile delinquency was increased in many cities by war conditions. Especially notable was the increase in the number carrying concealed weapons.

Automobile Fatalities in 1918.—The National Highways Protective Society, in its annual report, shows that the total toll taken by motor cars throughout the State of New York during the past year was 969 persons. The deaths from automobile accidents in New York City numbered 528, as against 417 for 1917. Of 441 fatal accidents outside the metropolitan area 416 occurred between April 1 and December 31, and only 25 between January 1 and March 31. Col. Edward S. Cornell, president of the society, recommends the enactment of a law in New York State similar to the statutes which have proved their worth in Connecticut, New Jersey, Massachusetts, and Maryland. The New Jersey law has been responsible for cutting down the number of fatal accidents from 245 in 1917 to 197 last year.

Hospital Asks Help.—Owing to the unusual demands made on its resources because of war conditions, St. Mark's Hospital, New York, states that it is urgently in need of money, and asks the public to come to its assistance. The hospital has recently increased its beds to 150. Last year, 126,227 patients were taken care of; 180,627 free hospital days of treatment were given, and the number of visits made by poor patients was 229,405.

Charges Against Hospital Management Unfounded.—The charges recently made against the financial management of the Bronx Hospital Association are characterized as preposterous and slanderous by the president of the proposed hospital, Dr. Alexander Goldman. The former manager of collections made the charge that as a result of waste of money, extravagance, and maladministration the greater part of $150,000, which was collected for the hospital fund, had been dissipated. Dr. Goldman states that less than one-third of this sum was collected, that the books of the institution have been carefully audited by a certified public accountant and are open to inspection, especially by the State Board of Charities. The latter organization states that it has no jurisdiction inasmuch as the Bronx Hospital Association has not accepted city or State funds. The Bronx Hospital Association purchased the old Eichlen mansion at Fulton Avenue and 169th Street last May, which it planned to equip as a hospital building by September 1.

Doctors Charge Illegal Conspiracy.—The Medical Association Realty Company, Inc., of Brooklyn, made up of twenty-five physicians, acquired property on St. Marks Avenue, where it planned to conduct a sanitarium. It is now bringing a damage suit for $50,000 against certain residents in the vicinity on charges of an alleged conspiracy to prevent the erection and maintenance of a sanitarium at 746 St. Marks Avenue. It is alleged that the defendants influenced the United States Title Guarantee Company to withhold a loan of $20,000 necessary to erect the sanitarium.

Influenza Again on Increase.—During the week ending January 4 there has been a recurrence of the influenza outbreak in New York City. The number of cases being reported daily to the Department of Health has suddenly increased from one to two hundred daily during the past four or five weeks to 415 on January 3 and 549 on January 4. The number of pneumonia cases also showed an increase for this period. Health Commissioner Dr. Royal S. Copeland prophesied that there would be an increase in influenza and pneumonia in New York as a result of the overcrowding and exposure incident to the celebration of the arrival of the United States Navy. A very decided recurrence of the epidemic is reported from Providence, R. I.

The New York Physicians' Association in its annual meeting elected the following officers: *President*, Dr. Israel Grushlaw; *First Vice-President*, Dr. John Morely Hitzrot; *Second Vice-President*, Dr. Samuel Kleinberg; *Treasurer*, Dr. Alfred Hellman; *Secretary*, Dr. Morris Grossman. The next meeting of the association will be held at the Chemists' Club on the night of January 23, 1919. Dr. Solis Cohen of Philadelphia will read a paper entitled "Lessons from the Two Grippe Pandemics."

Dr. Simon Flexner of the Rockefeller Institute for Medical Research, New York, has been appointed an officer of the Legion of Honor by the French Government. Dr. Flexner was also elected president of the American Association for the Advancement of Science, at its annual meeting in Baltimore, on December 27.

Dr. John P. Davin of this city has been mentioned as a possible nominee by Governor Smith for the office of drug commissioner. If we must have a State drug law, Dr. Davin would make a good commissioner, and the interests of the medical profession would be safe in his hands.

Obituary Notes.—Dr. JEREMIAH PHELAN of Brooklyn, N. Y., retired, a graduate of the Long Island Hospital Medical College, in 1884, died, after a year's illness, in St. Peter's Hospital, Brooklyn, on January 2, aged 60 years.

Dr. DONALD H. CURRIE of the United States Public Health Service, physician of the port of Boston, died at his home in Brookline, Mass., of pneumonia, following influenza, on December 23, aged 42 years. He was a graduate of Washington University Medi-

cal Department, St. Louis, Mo., in 1897, entered the United States Public Health Service in 1899, and served eight years in Hawaii, where he did research work among the lepers of Molokai, the value of which was recognized by medical men throughout the world. He was the United States representative to the Leprosy Congress in Bergen, Norway, in 1909. Dr. Currie was also associated with Dr. Rupert Blue in fighting the bubonic plague in San Francisco and yellow fever in New Orleans.

Dr. JOHN P. HUSSEY of Providence, R. I., died suddenly of acute indigestion and dilatation of the heart on December 19, aged 46 years. He was a graduate of the Georgetown Medical School in 1903.

OUR LONDON LETTER.

(From Our Own Correspondent.)

REHOUSING AND MEDICINE — THE PURCHASE OF GLYCERIN AND ALCOHOL—THE INCIDENCE OF DENTAL CARIES—DEATH OF DR. GEORGE OGILVIE—WHEN IS A MAN DRUNK IN THE EYES OF THE LAW?

LONDON, December 21, 1918.

COMMON to nearly all the election addresses of parliamentary candidates, male and female, was the promise to support in every conceivable way a Government scheme for rehousing. What the actual shortage of houses may be no one can say, while it is clear that different people will have different standards not only as to the amount of houses that must be built but as to the quality of house property which ought to be abolished. Further, while many persons already find it extremely difficult to get houses where their business lies, many other persons are grossly overhoused. The former class by gradual backward pressure, using up too much space both in town and countries, give rise to the domestic overcrowding, at the periphery of poverty, which lies at the root of so much physical pain and disease. The overhoused form a standing argument for the doctrines of extreme socialism, along which lines at the present moment imperial progress will hardly be made. Where everybody wants to tidy up everything simultaneously, nothing can happen but muddle and no rehousing scheme, dependent upon an evident dispossession of the wealthy, will take place. The medical profession is profoundly interested in the immediate starting of practical schemes for the rehousing of the poor and do not want to wait for the millennium. The best efforts of preventive medicine are defeated by the domestic environment in which twenty-five per cent. of the population of these islands reside, and, what is more dangerous, other measures of preventive medicine are paralyzed naturally, though quite unnecessarily, by the feeling that they will be ineffective when administered in the existing lamentable environment. The Local Government Board has issued a circular with reference to the housing of the working classes in which the extreme urgency of the matter is referred to, remembering the problems which will arise in connection with demobilization and the setting free of labor and materials for civil purposes. Of course it does not matter what grounds the Local Government Board gives for urgency, but to medical men it will seem that far more urgent reasons than those alleged have been rampant for years. The work of preventive medicine has been hindered for example. The Board has circularized the Councils of Metropolitan Boroughs, and the urban and district councils, those being the three forms of local authority, and requested definite information as to whether the local authority will provide the houses necessary for the working classes of their own district at an early date in accordance with the Board's terms, and when any building schemes will be ready for submission. The circular also asks how many houses will be provided; if the sites have been selected or acquired; and if there is any work such as the development of sites and construction of roads, sewers, etc., awaiting approval. Upon this information the President of the Local Government Board should be in a position to advise the Government as to whether the local authorities can be relied upon to provide the necessary houses, or whether other measures must be taken to ensure their provision; and it is the general belief that the latter course will be necessary. The housing question is not considered to have received adequate attention from the late President of the Local Government Board, Mr. Hayes Fisher, the activity of the Department bearing no relation to the importance of the information placed in its possession by local authorities over a year ago. At that time nearly 1400 local authorities replied to a departmental questionnaire that houses were needed within their areas, and of these over a thousand intimated their willingness to build, and the joint result of these replies was an estimate from the Local Government Board that about a quarter of a million houses would be required. One year later, namely, last summer, it turns out that definite building schemes for eight thousand houses, meeting the needs of eighty-four local authroities, have been approved, while the plans for the building of eight thousand other houses are awaiting revision. Shortly after this position of the housing question was revealed, Mr. Hayes Fisher resigned in favor of Sir A. Geddes. It seems fairly clear that at such a rate of progress, the further measures contemplated will have to be taken. The metropolis seems to have been more generally progressive than the provincial centers and for once in a way in a public health problem aggregation of material has not in itself been a drawback. The Housing Committee of the London County Council has reported that 92 metropolitan authorities have resolved at a conference that all the local authorities of Greater London should cooperate in working out housing schemes. In view of the difficulties of building anticipated for seven years after the war, and the high cost of slum property, the Conference went on to urge legislation for accelerating and cheapening the acquisition of such property. Legislation along this difficult path has been promised for many years, and many of those medical men who take an interest in current politics believe that this is the most promising direction in which to speed up great rehousing schemes. The housing ques-

tion is undoubtedly at the bottom a question of access to land, both for the site of the house and for the materials so that the opening up of land is an absolute necessity.

The Ministry of Munitions, whose activities are now coming to a close, has just made public notification that the purchase of glycerin and alcohol for domestic purposes is again legitimate, subject to the conditions under the Board of Customs and Excise in the case of the latter commodity. The manufacturers should now be able to obtain their requirement of alcohol for industrial purposes, but in Great Britain the finer chemical industries and extensive research alike suffer under the inability to purchase alcohol at a reasonable rate. Pharmacologists will welcome the presence of glycerin among things that can be prescribed and employed freely.

Major Nickolls Dunn, of the Horton War Hospital, Epsom, makes an urgent plea for a thorough examination, if necessary, through the medium of a royal or departmental position, into the cause of dental caries. This has been often done before but Major Dunn makes the shrewd plea that if the inquiry were held *now* the etiology could be very satisfactorily discussed because such a large number of the subjects have clearly not been subjected to one of the two causes, to which dental caries is most usually attributed, viz., abuse of sugar, and use of white flour. Sugar has been at a very low ration for some time and no children under four, and probably under five years, can possibly have had too much. White flour has also been prohibited, and only flour in which a high percentage of husk remained could be obtained. Yet caries continues. Major Dunn asks: Why does the tooth, the hardest part of the body, rot in the nursery and the school room? and the question badly needs answering. The misery due to dental caries has been extreme among the soldiers when serving in distant zones of war where proper dental attention could not be obtained; and even where facilities for remedial interference might have been expected, they were not full provided for the whole country is short of qualified dentists. The question of making it illegal to act as a dentist without a qualification is a difficult one. Some say that if an act penalizing the unqualified were passed the improved prospect of the qualified would lead to a swelling of their ranks. Others point out that qualified men could never be expected to practise dentisty as a single profession in a thinly peopled locality unless he made his fees high—when probably no one would support him, and *sub rosâ* quacking would reappear.

The death is announced at the age of 66 of Dr. George Ogilvie, who was for many years a well-known London consulting physician, with a remarkably cosmopolitan practice. He was educated at the University of Edinburgh, but made full use of the linguistic opportunities offered by much post-graduate work in Paris and Vienna, and became a fluent conversationalist in French and German. Later he learned Spanish, and in all three languages his services were generally used by the medical profession when it was necessary to address foreign medical guests in their own tongue. Ogilvie made these speeches very happily.

The transactions of the Medico Legal Society over the period of the war, *i.e.* 1915-1918, have just been published and among the papers will be found an interesting essay, entitled, "Drunk in the Eyes of the Law," by Dr. F. J. Smith, physician to the London Hospital, and the president-elect of the society. The whole question of what is meant by "drunk" becomes a difficult one when drunkenness, as so often happens, complicates an illegal action. How great an effect must be produced by alcohol upon a person before he can be called "drunk" and receive the benefits or pains attached to the condition? Some medical men have one standard and some another, and Dr. Smith urges that the question which the Inebriety Act in Section 1, requires to have answered is: "Would the accused have done what he did do if he had not taken the alcohol?" The evidence which the doctor can collect as to confusion of ideas, slurring of speech, want of due balance of body, and so on may form contributory proof that the suspected individual is under the influence of liquor, and from such evidence the basic question can be answered by the medical men up to a certain point, beyond which the examiner will have to form individual conclusions. But Dr. Smith's definition of the term will have great use in law courts if it becomes accepted, because there will be no quarrel among rival witnesses as to how drunk a person is, the only question being did he do the thing *because*, and *only because* he had had alcohol.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

INFLUENZA—THE FIRST TRAIN FOR LILLE—GERMAN ATROCITIES AT LILLE—THE THERAPEUTIC USES OF PIE—STUDY FOR THE SOLDIERS KEPT IN FRANCE.

PARIS, December 2, 1918.

THE decrease in the influenza epidemic in Paris turns out to have been more apparent than real. The number of deaths during the 43d week (ending October 26) of the year was the largest since the beginning of the epidemic. The daily returns for the 27th, 28th and 29th show an increase, the 29th having a total of 230. It appears from particulars of ages that the greatest mortality is among adults between 20 and 50 and that women pay a greater tribute than men. The figures are: Up to 2 years, 16 males, 10 females; from 2 to 9 years, 12 males, 36 females; from 10 to 19, 68 males, 98 females; from 20 to 39, 212 males, 493 females; from 40 to 59, 100 males, 122 females; 60 and over, 38 males, 58 females; total, 446 males, 817 females.

The first train for Lille left the Gare du Nord on Sunday evening. The station bore a holiday aspect. Many refugees who, as every Sunday, came from different meeting places to crowd the railroad trains were eager to be among the first to leave for the recently liberated capital of French Flanders.

Regular trains are not yet running on the old schedule passing through Longueau, Amiens, Arras, Douai, and Lille. It is necessary first that the roads be put into condition to permit the maintaining of a regular service. The train for Lille is the Calais train. One may now leave Paris at 8.05 o'clock, arriving at Calais at 6.43, reboarding the train at 7.15

for Saint André, on the outskirts of Lille, at 10 o'clock in the morning. For the present the train cannot go farther.

There were numerous passengers on the 8.50 train, but only a few held the coveted tickets (that a great many collectors would be happy to obtain). The manager had issued fifty-one tickets for Lille, as one cannot go there without the necessary authorizations of the Prefect of Police, certified by the British Staff Office. The few inhabitants of Lille, the first to be permitted to go back to that city, were afforded comforts. Joy was seen radiant in their faces. Some of them cried, so great was their emotion. The hour approached, the moment of last confusion. The doors were closed. Along the length of the platform a guard shouted: "Passengers for Lille, all aboard!" Exclamations of joy were raised as each one repeated: "Lille! All aboard!" It was fifty months ago since they had heard that shout in the great station.

The permanent secretary of the Academy of Medicine at the last meeting read an address signed by the savants of Lille detailing and protesting against the atrocities committed by the Germans during their occupation of that city. It will remain for history, said they, to judge of the destruction, the incendiarism and all of the other ruthless acts which may be attributed to acts of war, but they registered their protest, said they, against the deportations and against the tortures inflicted upon the civil population. During the Easter season of 1916 ten thousand young girls and women were torn from firesides and carried into Germany, where they were subjected to such shameful treatment as to be unspeakable and were treated no better than if they were beasts. The slightest protest on their part was instantly visited by violence without ceasing.

At a little later period they arrested the young men and all of the girls between 18 and 14, as well as the aged men, and put them to work in the front lines subjected to the fire of their own people. Many were killed.

Then came the selection of 1,000 hostages, 400 of which were women chosen from the intellectual and élite of the city. They were compelled to travel 8 days and 8 nights crowded into freight cars, and were thus conducted into Poland in mid-winter, and as an act of reprisal were compelled to work in occupations of the most degrading character. A great number of this martyred company succumbed. We can never pardon nor can we ever forget this flagrant violation of human rights. For these unspeakable outrages, planned and executed with studied cruelty by General Solner and his aide-de-camp, Colonel Hemmel, the German people can be held responsible, as the soldiers in general participated in all of them.

The Academy was profoundly moved by the reading of this letter, and immediately appointed a committee to prepare the reply which follows and which was voted without a dissenting voice: "The Academy is deeply moved by the letter signed and sent to them by their brother savants of Lille. The Academy has decided with them to cease all relations with the German savants who do not solemnly declare that they actively opposed the inhuman actions of their compatriots. The Academy bears an inexpressible admiration and desires to offer its united and brotherly salutation to the noble souls so cruelly subjected to the unspeakable horrors of a brutalized enemy."

Doctor Capitan presented at this meeting a report of exceeding interest on grippe with grave complications of bronchopneumonia. He treated with two remedies 208 cases in his service, one remedy being arsenic and the other colloidal silver, but of 40 cases which were considered as hopeless he succeeded in saving 50 per cent. Immediately following the injections the temperature fell and remained at normal after a period of 2 or 3 days. The pulmonary congestion rapidly disappeared with a profuse expectoration.

Pie is not among the articles treated of in works on materia medica, but a recent incident shows that it may have therapeutic value. In a hospital lay an American sailor, for whom everything had been done by surgeons, doctors, and nurses, and yet something was lacking. He was homesick; his mind was ever away in a little Atlantic coast town. Nothing that the good people this side of the world could do could console him. It was home that he craved, and his yearning thoughts groped for a symbol—a visible, tangible token of far-away Massachusetts. He wanted something that he could touch and say to himself: "This is a bit of home." One day, in the midst of his bodily pain and soul-suffering, there flashed upon him the object of his quest, and he murmured excitedly: "Oh, if I could only have a piece of mince pie." It was not that he wanted to eat a piece of pie, for he was too ill for that. His hunger was for what the pie represented. An American nurse who heard the wish managed, with some difficulty, to find all the ingredients for a real New England pie. When she took it to him she put with it a bit of cheese, also hard to procure in these times, so that nothing would be lacking, and in the cheese she planted a miniature Stars and Stripes. The poor boy could eat neither the pie nor the cheese, but they contributed just the home touch needed to improve his condition. When the wife of the American Consul General visited him a few days ago she remarked upon the improvement in his condition, and he said: "Two days ago I was in such misery that I could have welcomed death. Now I feel that America is not so far away as I thought and that I have got to hang on."

And more and more the boys are learning to pass the days and weeks of convalescence from their wounds in healthful reading and study. A thirst for knowledge, and especially for technical training, is everywhere being produced among young Americans by the experience of war. This fact led a distinguished visitor this week to ask the question: "What is to be done for the many thousands of American soldiers who will necessarily remain in Europe for some time after the cessation of hostilities?" It has been suggested that the great American universities, and especially the technical schools, may be led to establish courses of instruction for the Americans, perhaps in connection with the French and British universities, so that the soldiers may return to America better equipped than ever before to fulfil their part in the new era of national life.

1. Prophylactic Inoculation Against Pneumonia: A Brief History and the Present Status of the Procedure.—E. A. Fennel gives a brief historical review of this subject, showing how the discovery of Neufeld and Händel, in 1909, that a certain strain of disease producing pneumococci could stimulate, in an animal, a specific immunity response to that one particular strain, led to an investigation of the groups into which pneumococci might be divided, on a basis of their ability to stimulate *specific* antibody production. Classifications of these groups were published independently by Dochez and Gillespie in America and by Lister in South Africa. The four groups of the American observers are well known, but Lister on account of the greater multiplicity of groups prevalent in South Africa was able to carry his classification further, *i.e.* into ten groups of pneumococci classified according to their group antigen qualities and another unclassified group "X" into which he places strains which give rise to no antibody production when injected into animals. Of these groups, A, B, and C are of prime importance on the Rand, while group H, in a localized epidemic, suddenly sprang into prominence. The relative importance of these types, as measured by the incidence and mortality of the pneumonias caused by them, varies from time to time and with localities, a fact which might have received more recognition than it has. This point was well illustrated in the influenza pandemic, and attention was drawn to it by Friedlander and his coworkers, who found an incidence of about 80 per cent. of Type IV in their pneumonias at Camp Sherman. The results obtained by Lister in his work on pneumococcal vaccination are startling, and his Crown Mine Experiment is of particular interest. During a nine months' period approximately 11,000 natives were inoculated with a vaccine that included groups A, B, and C. Eighty-two cases of lobar pneumonia resulted, but not a single case was caused by any one of the three groups contained in the vaccine. Had the prevalence of these groups remained constant with the other types, cases due to these groups A, B, and C to the number of 120 would have developed. It would seem from Lister's observations that an effective vaccine should be almost 100 per cent. efficient for the specific types. Lister inclines to large doses and considers a total of 6,000 million cocci as the minimum; three inoculations at intervals of seven days are necessary. The work of Lister has been confirmed in this country by Cecil and Austin, who prepared a saline pneumococcal vaccine of Types I, II, and III, which was used at Camp Upton to vaccinate 12,519 men. The vaccination of troops began February 4, 1918, and was continued for about ten weeks; three inoculations were given at seven day intervals, except in cases which showed a marked reaction after the first or second dose, when inoculation was discontinued. The results showed that Types I, II, and III vaccine seemed to prevent cases of pneumonia due to those types and also caused an apparent protection against Type IV and against *S. hemolyticus* and *S. viridans*. Fennel suggests that this apparent protection may be due to a mobilization of ferments and leucocytes caused by the injection of foreign protein and therefore increased natural resistance, or that the change in ferment-antiferment balance has conferred on the individual, besides a specific immunity, an additional resistance against a large number of other bacterial invaders. Saline vaccines, however, have the disadvantage of rapid autolysis; furthermore, saline injections are frequently followed by a sharp reaction. These disadvantages are overcome by the use of lipovaccines, which may be given in massive doses; and it would seem that that oil not only retards absorption but reduces toxicity. A triple pneumococcus lipovaccine has been perfected and is now in use in the military camps. Such a vaccine is rather more laborious to produce than the saline vaccine, and the necessary equipment is more expensive. While it is too early to judge of the results of inoculations—during October and November, 1918, the Army Medical School prepared and sent out more than two million doses of vaccine—in addition to the specific immunity conferred, a freedom from respiratory diseases in general seems to have followed the use of the vaccine. Experiments would seem to show that lipovaccines render the mouse more susceptible to large doses of streptococci, but more resistant to smaller doses; and this may explain some of the so-called "cross-protection" results. The author concludes: (1) That prophylactic pneumococcus vaccination is successful over an extended period of time for those groups represented in the vaccine. (2) That a pneumococcus lipovaccine, of slight toxicity, to be given at one injection, has been elaborated, and has had widespread use, and that early reports indicate its usefulness.

4. Hemorrhagic Bronchitis: Castellani's Bronchopulmonary Spirochetosis.—H. Violle found a number of cases of broncho-spirochetosis in France in 1916. At Toulon a comparatively large number of cases occurred among native troops from the Far East, and also in Europeans. The disease was first discovered by Castellani in Ceylon in 1905 and since then has been noted by various observers in the West Indies, the Philippine Islands, India, and other tropical countries. The symptoms observed by the author in France were: Hemoptysis, the case generally having been diagnosed as tuberculosis, and the expectoration being of a peculiar vivid pink; and frequent cough, worse at night. Physical examination of the chest often revealed little or nothing; in some cases there were signs of bronchitis with or without emphysema, or signs of consolidation. The general condition of the patient was often good, and frequently there was no fever. There may be a slight degree of anemia in such cases but the number of leucocytes is normal, as is also the leucocyte formula. Microscopical examination of sputum reveals enormous numbers of the *Spirocheta bronchialis*, an organism which varies in length, shape, and number of spirals. The length may be from 4 to 30 microns, and is usually from 7 to 14. According to Fantham, the medium forms are derived from long ones by transverse divi-

sion. Certain of the spirochetes have very few spirals; others have a large number very close together. This spirochete has not yet been cultivated. The author has not been able to reproduce the disease in rabbits, guinea pigs or pigeons, but Chalmers and O'Farrell have done so in a monkey by intratracheal injections. The disease is very contagious, probably by means of "coccoid bodies" derived from the spirochetes. The author believes that this spirochete may be present in small numbers in many individuals, as is the case with the pneumococcus, and that with lowered vitality of the tissues they may multiply and invade the whole of the bronchopulmonary system. In regard to the possibility of infection spreading from the mouth to the bronchi, none of the author's patients had any mouth lesions of spirochetal origin and their teeth and gums were in good condition. Diagnosis is based on finding the *S. bronchialis* in the expectoration in the absence of the tubercle bacillus, of hyphomycetes and of ova of *Paragonimus westermanii*, Kerbert. Clinically, if a patient exhibits bloody expectoration of a vivid pink color and is in good health, broncho-spirochetosis should be suspected. Cases of mixed infection occasionally occur. Prognosis, as a rule, is favorable. Symptoms may disappear in three to four weeks. Relapses seem to be frequent, and chronic forms occur with mucopurulent, greenish, or bloody expectoration. In many cases, rest, nourishing diet, and country air effect a cure. Ergotine and tr. iod., a few drops well diluted, should be given if hemoptysis is severe; and if there is much secretion and cough is painful, opium preparations may be given. Arsenic and tartar emetic and arsenobenzol have been used in treatment and may be indicated in chronic cases. The possibility of this disease should be remembered in cases of hemoptysis. Correct diagnosis is important, not only to relieve the patient's mind of the fear of tuberculosis, but also from a medicolegal standpoint, since tuberculosis entails permanent discharge from the Army with pension whereas bronchial spirochetosis merely means a few weeks rest for the patient.

6. The Treatment of Extensive Septic Wounds.—H. Gardiner describes a method of treatment for septic wounds with extensive discharge without a permanent dressing. Incisions and openings are made as usual but with the idea of obtaining the maximum effect of gravity in the subsequent treatment. The wound is then packed with gauze and bandaged in the usual way in order to stop oozing of blood. Forty-eight hours later all dressings are removed. The wound is syringed with a mild antiseptic, and a guard of perforated zinc cut to appropriate size and bent in the form of a cradle, placed over the wound and covered with a sterilized towel. If possible, an ordinary cradle is placed over the whole. The discharge is allowed to run out from the wound and is taken up by a sterile pad of wool or spagnum moss, placed so as not to touch the wound. The wound is then syringed and swabbed at intervals, on an average twice a day. This treatment is continued until all pockets and recesses have been closed by granulation, the granulated surface is smooth, and the discharge has practically ceased. The wound is then dressed in the ordinary way with gauze and wool. The difficulties experienced in this method of treatment have been threefold: (1) The difficulty of arranging the wound by operation for opening pockets and of altering the position of the patient so as to obtain the greatest effect of gravity; this may be partly overcome by the judicious use of gauze wicks and by frequent cleansing of the wound by syringing. (2) The difficulty of continuing the treatment at night, when patient is restless. The limb may be placed in a splint or an ordinary dressing and bandage applied at night in cases where it is necessary. (3) It is difficult to keep the neck and side of the trunk covered at night. In some cases a rampart of spagnum moss may be built up round the wound and kept in place with a towel or bandage. The advantages of the method indicated are: (1) Perfectly free drainage. (2) Absence of tendency to pocket, provided the wound is exposed and arranged so as to allow gravity its maximum effect. (3) Absolute painlessness of dressing even the most extensive wounds. (4) Dressing can be performed without manipulation of the wounded part. (5) A great economy in dressings is effected. The author points out that the edges of wounds so treated may tend to become hardened and small scabs may develop. These should be removed at once and can usually be prevented from forming altogether by careful cleansing and swabbing of the wound. In case of deep pockets in the wound, a rubber drainage tube should be employed to prevent premature closure.

1. The Bent Back of Soldiers. Lieut.-Col. A. F. Hurst.
2. Some Remarks on the Morbid Anatomy and Histology of Rheumatoid Arthritis. T. P. S. Strangeways.
3. Observations on the Cause of Rickets. D. Noel Paton, Leonard Findlay, and Alexander Watson.
4. Vanghetti's Operation. Major W. F. Brook.
5. Hysterical Tremor. Major W. Johnson.
6. Preliminary Note on the Complement Deviation in Cases of Malaria: A New Aid to Diagnosis. Captain J. Gordon Thomson.

3. Observations on the Cause of Rickets.—D. Noel Paton, Leonard Findlay, and Alexander Watson were led to produce rickets in a number of young dogs on account of the difficulty of getting satisfactory material from children to enable them to carry out their investigations on calcium metabolism in this disease. Previous observations made in the same laboratory—the Physiological Laboratory of the University of Glasgow—had shown that rickets could be induced by simply keeping the pups in the animal house. It had also been shown that thymusectomy had no effect on the onset of the disease, and an extensive study of factors in the causation of rickets had seemed to show that some factor other than diet was involved. As a result of their own investigations the authors found: (1) That pups kept in the country and freely exercised in the open air, although they had actually a smaller amount of milk fat than those kept in the laboratory, remained free of rickets, while the animals kept in the laboratory all became rickety. The observations seemed to show that some other factor than diet is the prime cause of rickets in dogs, and afforded no evidence that milk fat (butter) contains any accessory factor protecting against the development of rickets.

6. Preliminary Note on the Complement Deviation in Cases of Malaria: A New Aid to Diagnosis.—Captain J. Gordon Thomson has succeeded in preparing a specific antigen for malaria in the following manner: He made a culture of malaria parasites from a heavily infected case according to the method described by J. G. and D. Thomson (1913). After twenty-four to forty-eight hours' incubation, the supernatant fluid was pipetted off and an excess of distilled water added to the remaining corpuscles. This was then shaken up and centrifuged, the supernatant fluid being removed each time. This process was repeated until the fluid was quite free from hemoglobin. The sediment at the bottom of the centrifuge tube then consisted of the bodies of malarial parasites, the washed envelopes of red cells, and leucocytes. This sediment was then dissolved in as small a quantity of decinormal sodium hydrate as possible, and a straw-colored viscid fluid obtained. This was neutralized by adding normal hydrochloric acid solution drop by drop. The more numerous the malarial parasites and the less fluid used in dissolving them, the stronger the antigen will be. This solution was then diluted ten times with normal saline and its anticomplementary action tested by titration with varying dilutions of guinea-pig's serum. Further dilutions should be carried out until an antigen is obtained which does not of itself prevent the action of complement. This antigen was found to act well diluted 1 in 30 with normal saline. Its anticomplementary powers were found to vary enormously and it may be necessary to dilute the original antigen one hundred times. The higher the dilution, of course, the weaker the antigen, and the aim should be to obtain as strong an antigen as possible which is not too anticomplementary. The author has used an antigen composed of ten different strains of benign tertian malarial parasites with satisfactory results; it gave a positive reaction with known cases of benign and malignant tertian malaria. The antigen must be titrated before use to estimate the minimum dose of complement required. Patient's serum is diluted 1 in 10 with normal saline, and for

each serum four test tubes are put up, three containing antigen and the fourth being the serum control. Two and a half, three, and three and a half doses of complement are introduced into the tubes containing antigen, and two and a half doses are added to the serum control. An antigen control is put up with each series. The method used is long fixation in the cold, the tests being kept overnight in the ice chest. In the morning the sensitized red cells are introduced and the results read after fifteen minutes in the water bath at 37° C. Readings must be carefully taken immediately after the negative controls; serum and antigen controls show complete hemolysis. The author has performed tests on the serums of 200 known cases of benign and malignant tertian malaria, with and without parasites in the peripheral blood, and at all stages of treatment by quinine. Positive results were obtained after short courses of treatment and in some cases after a considerable amount of treatment; but the reaction becomes weaker. As a rule, after prolonged treatment and in cases where there has been no attack of malaria for many months, the result was negative. Great care is essential in the performance of this test; the serum should be drawn with aseptic precautions into sterile tubes and should be used as soon as possible after being taken from the patient. Serums of syphilitic patients give a positive result and therefore this disease must be excluded. This preliminary note is published by the author so that others may make collateral studies with a view to obtaining a test sufficiently delicate to indicate complete or nearly complete recovery in the case of a patient who has been suffering from malaria.

The Diagnosis of Syphilis by the Sachs-Georgi Precipitation Method.—M. Mandelbaum has very greatly simplified the technique of the diagnosis of syphilis by flocculation. Three drops of fresh human non-inactivated serum are mixed with one cubic centimeter of a NaCl solution and inactivated by heating at 56°C, for one-half hour. Then half a cubic centimeter of a cholesterinated extract of calf's heart, to a dilution of 1/6, is placed in the oven for two hours and then allowed to remain during the night at the room temperature. The flocculation represents a positive result. The results offer a concordance with Wassermann's reaction in some 91 per cent. of the cases. It is more sensitive and also much more simple than the original procedure of Sachs and Georgi, who utilized, in principle, the precipitation of the globulins under the favorable action of cholesterin.

The Heart in Myxedema.—H. Zoudek describes the radiological and the electrocardiographic changes of the heart in cardiac insufficiency of thyroid origin. By the use of the fluoroscopic screen the writer detected a dilatation of the heart on both the right and left sides, attaining considerable dimensions. At the same time the contours were irregular and the contractions only slightly visible. There was bradycardia with a normal systolic tension. An appropriate opotherapeutic treatment resulted in a decrease of the cardiac diameters quite as striking as the psychic improvement resulting from the treatment. The number of pulsations, likewise their amplitude, was increased. Zoudek is of the opinion that there is a direct action of the thyroidine on the myocardium. The electrocardiogram of the myxedematous heart denotes an absence of an auricular wave as well as a telesystolic wave. Here, again, opotherapy causes the normal type of contraction to reappear.

Radioscopy.—H. Chaoul describes a radioscopic apparatus which can be used in daylight. It is a kind of dark room, the image on the screen is reflected by a visible mirror through a lateral opening. The screen can be replaced at no matter what moment by a photographic box, which allows one to seize exactly upon the instant that a radiography presents its optima. The same apparatus allows one to reduce a dislocation or a fracture under the permanent control of radioscopy and avoiding any maneuver in darkness.

An Experimental Study on the Treatment of Spirochetal Diseases with Salvarsan.—W. Kolle offers a really important paper giving the results of his researches which are the continuation of the work carried out in Ehrlich's laboratories. The new combinations constructed chemically according to *a priori* reasonings were experimentally essayed in rabbits. For this purpose, Kolle possessed a strain of spirochetes acclimated to the rabbit, which transmitted syphilis by inoculation experiments from one animal to another, sometimes even by coitus. The period of inoculation in the rabbit is from twenty to twenty-five days. The majority of untreated animals offered general manifestations of the disease comparable to secondary manifestations in man. The new preparations were experimented with in inoculated rabbits from the viewpoint both of their toxicity and their therapeutic action (estimated by the disappearance of the spirocheta, the possibility of reinfections, etc., the serologic reactions being inapplicable in rabbits). The chemio-therapeutic quotient allows one to estimate the value of each medicament, abstraction being made of the difficulties in applying to man the experimental results obtained in the rabbit. The quotient is represented by a numerator: the smallest curative dose, and a denominator: the largest dose tolerated. It is all the smaller the greater the utilizability of the given preparation. The various products studied were salvarsan, neosalvarsan, galyl (French), and finally salvarsan-silver-sodium, which the writer calls excellent and which possesses the lowest quotient (1/25-1/30) and is readily soluble. It also offers a neutral reaction. The writer proposes to publish the therapeutic results obtained in man with this product in an article to follow. He likewise announces a new product which he mysteriously designates Salvarsan 1495, but says its composition "cannot be revealed on account of the enemy."

The Bacteriology of the Present Influenza Epidemic.—F. Neufelol and P. Papamarku conclude that Pfeiffer's bacillus is the pathogenic agent of the pandemic.

The Culture of the Influenza Bacillus.—K. Hundeshagen recalls the fact that Pfeiffer's bacillus grows particularly well when cultivated with other bacteria. Theoretical considerations led the writer to add hemolyzed red blood corpuscles to the culture media which possess the same action as the added bacteria and favor the growth of the Pfeiffer to a great extent.

September 14, 1918.

The Appreciation of Visual Defects in Its Relation to Expert Examination in Cases of Demands for Damage During War.—E. Klauber merely recalls the difficulty of determining in certain cases the part played by an affection acquired during the war and from the fact of the war and that of spontaneous disease. Thus, in the class of advanced age, the majority of cases of physiological presbyopia are the object of requests for indemnity, for the simple and only reason that soldiers attribute all that may have happened to them to the war. The writer recommends an expert examination of the ocular status of every demobilized soldier, in order to utilize it as a basis for any ulterior demand for indemnity.

Urethral War Wounds.—E. von Hofmann relates fifteen cases of wounds of the urethra. The writer does not offer any new surgical procedures, a fact that has been most striking both in German and Austrian medical literature since the war commenced. Hofmann estimates the total mortality of urethral wounds at 26 per cent. Urethral wounds, uncomplicated by fractures, intestinal lesions, etc., do not give rise to death. On the other hand, in wounds of the urethra complicated by other lesions, the death rate reaches 57 per cent.

Influenza Still Exists in Italy.—Micheli and Satta write of the current epidemic of influenza in connec-

tion with a research on the occurrence of three-day fever during the past three summers. While in Spain the pandemic came and went very quickly the disease in Italy goes back to about the same date but new foci continue to crop out. There were evidences of the disease in May and June, but it was not until the end of July that especially in the Piedmont region a sharp recrudescence took place, after the former visitation had been pronounced extinct. The three-day fever still was recognizable, and upon this basis, as it were, influenza rapidly spread under conditions favorable for epidemicity. Unlike the earlier visitation the disease created alarm from its extreme contagiousness and severe type. There could be no doubt that it was the old influenza of 1889, detail for detail. Pneumonic complications were present in from 10 to 15 per cent. The favorite age incidence was 17 to 40. The elderly and invalid furnished some of the deaths. During the first month of the revived disease the case mortality was 5 per cent. The autopsies showed remarkable correspondence of type. The authors profess to have evidence that the first beginnings of the influenza in Spain were at the end of April instead of the end of May. Should this be the case much could be accounted for which has been obscure. The malady could have spread to France and Italy by May or contemporaneously with the great explosion in Spain. The authors therefore think the name Spanish Influenza should stand. The benignity of the Spanish pandemic and the earlier cases in adjoining countries is also an argument for the Spanish origin, for the earliest outbreak has usually been mild. The increasing virulence is shown as the disease reaches Germany and Switzerland, and in the late summer outbreak in parts of Italy. The confusion between the first Italian cases in May and June with three-day fever is eloquent proof of its mildness at that period. The latent interval in Italy between the mild and severe type was about one month.

Correspondenz-Blatt für Schweizer Aerzte.

October 19, 1918.

Treatment of Severe Influenza with Convalescent Serum.—Liebmann states that at the end of June the severe character of the epidemic began to be recognized, with especial reference to lung complications and septic phenomena. Deaths began to accumulate with the final picture of extreme intoxication. Everything possible was tested, including convalescent serum. Do these patients secure any immunity toward new infection? If not, this serum would not be rationally indicated. The majority of patients do develop immunity of some sort or degree. It would indeed seem that recovery in the severe cases would be impossible without the development of antibodies. One writer, Scholz, saw no benefit from convalescent serum. The first case tested was one of lobar pneumonia with hemoptysis in a woman with a mitral lesion. She was seven months pregnant and the prognosis was apparently of the worst. The opposite lung became involved. The case was aborted by repeated injection of small doses of convalescent serum, and while relapse promptly followed it yielded to treatment in the same fashion. Whether the woman aborted is not stated, but apparently this could not have occurred as patient was "discharged cured" at a relatively early date. In a second case the woman was also a victim of lobar pneumonia, unilateral, and suffered two relapses. She recovered but three doses were necessary before the first fever abated. The relapses yielded promptly. Of two severe cases of double pneumonia, evidently croupous, one recovered and the other succumbed. Five other deaths from unilateral or bilateral croupous pneumonia are not included because of the lateness of the date when serum was exhibited. A long series of successes follows in which the action of serum was at times dubious, although in other cases prompt and efficacious. Every case seems to have been ordinary croupous pneumonia modified by the disease. The affection seems not to have extended above the lower lobes and was often unilateral throughout. Despite the relatively small involvement of lung tissue, however, the general disease picture was of the kind that is associated with grave prognosis. The absence of bronchopneumonia from this series is not commented on by the author, but had any of these cases been coexistent they surely would have been submitted to the same treatment. Although the author styles these cases grip-pneumonias and sometimes interstitial pneumonias, study of the cases shows that at least a good share were distinctly unilateral, with rusty sputum—the kind that usually terminate by crisis. There are no bacteriological reports submitted nor autopsy reports of fatalities.

Revue Médicale de la Suisse Romande.

October 20, 1918.

Mongolian Idiocy and Quadrupedal Gait.—Bourdillon refers to the well-marked characters of this form of idiocy which is not of frequent incidence—Comby saw 69 personal cases in 13 years. The author has recently seen two cases, one of which exhibited a form of behavior not hitherto described, as far as he knows. This was the quadrupedal gait, which was well marked; moreover, the suppleness of the joints, the acrobatic poses and tendency to mimicry suggested the Simian. Other behavior was much like that of some domestic animal, but this, of course, is commonly observed. The child loved to be petted, was itself affectionate, was docile and quite harmless. One could not call it ill for it showed full enjoyment of life and was apparently completely developed up to a certain point like an animal. There was no element suggesting a throwback to a Simian ancestor.

Lasegue's "Delire de Rêve" in a Menstrual Psychosis in a Debile.—Naville refers to the original description of this affection by Lasegue in 1881 under the name *Delire de Rêve*, while in 1894 Regis called the same phenomenon *Dream Delirium*. It occurs in various mental states, and in late years has been much studied by Freudians. As far as the author knows, it has seldom been seen in true psychoses. The patient was a debile who was also a microcephalic. When interned the case appeared to be one of frank hebephrenia. The subject had recently been employed as a chambermaid, and the mental symptoms had appeared suddenly. Save for a slight mental defect she was of average capacity, possessing good common sense and a good disposition. The attack in question began with a menstrual period, and she suffered habitually with dysmenorrhea associated with migraine. Before a true pathological condition developed her periods had been attended by irregular behavior, culminating in such frankly insane acts of self accusation, etc., that she was committed as irresponsible. Her mind cleared up after internment and she seems to have had considerable insight. Her fundamental mental defect became obvious and she showed the motor celerity of the microcephalic. She laughed continuously at times. Soon the peculiar dream state came in evidence when, after a nightmare, she related many happenings which in part concerned her past, which were of the nature of delirium. These dreams also pursued her during the day. After numerous monthly attacks she improved as her periods became less painful, and for the past four years has been comparatively well.

Mercurial Injections in Sodoku.—Borelli having in mind the supposed spirochetic nature of this affection, has tested injections of sublimate in the attempt to ascertain if the well known tendency to exacerbation is favorably influenced. The results appear to have exceeded anticipation, so unmistakable were they in this regard. However, the ultimate state of the patient in respect to cure has as yet to be determined.—*Il Policlinico.*

German Health Resorts.—The thermal and climatic stations of Germany and Austria before the war enjoyed an income of about 900,000,000 francs, while those of France received not much more than one-fourth of this huge sum. After the war the foreigner will visit France in preference to the Teutonic countries as a matter of sentiment and the French health resorts will have an unprecedented boom. The French statesmen look forward to this source of revenue as one of the principal ways of rehabilitating their country's prosperity.—*La Presse Médicale.*

Book Reviews.

THE DOCTOR'S PART. WHAT HAPPENS TO THE WOUNDED IN WAR. By JAMES ROBB CHURCH, A.M., M.D., Colonel Medical Corps, U. S. Army. With Foreword by Major General William C. Gorgas, Surgeon General U. S. Army. Illustrated. Price, $1.50. New York and London: D. Appleton and Company, 1918.

THIS is an exceedingly readable account of what is done for the wounded man from the time when and place where the wound is received to the final cure or loss at the base hospital. It is not, however, a bare recital of medical doings, but is rather a personal account of two years spent in France, at the front and in the interior, by an acute and accurate observer and a man endowed with much humor and a very human feeling for his kind. It is a book for the laity as well as for the profession and will interest both, though naturally more the doctor. The author has omitted the gruesome details of much that he saw, dwelling especially and by preference upon the cheerful side, the humor and the pathos and the heroism so abundantly displayed by the poilu. The work of Col. Church as military observer was done before the entrance of America into the war and so his account has not to do with the doughboys. He came across a number of Americans, however, who were fighting for France and for honor, and his meetings with them were often entertaining. This is one of the most enjoyable of the recent war books.

THE SURGERY OF ORAL DISEASES AND MALFORMATIONS, THEIR DIAGNOSIS AND TREATMENT. By GEORGE VAN INGEN BROWN, D.D.S., M.D., C.M., F.A.C.S.; Major Medical Reserve Corps, U. S. Army; Oral Surgeon to St. Mary's Hospital and to the Children's Free Hospital, Milwaukee, etc. Third edition. Price, $7.00. Philadelphia and New York: Lea & Febiger, 1918.

THIS edition is enriched with a chapter of 37 pages on War Oral Surgery which deals naturally with prosthetic and plastic work and is abundantly illustrated. Material is drawn from the most comprehensive sources. The first edition appeared in 1912 and underwent a thorough revision in 1917. The book has been slightly compressed so that there is no corresponding increase in bulk.

GENITOURINARY DISEASES AND SYPHILIS. By HENRY H. MORTON, M.D., F.A.C.S. Clinical Professor of Genitourinary Diseases in the Long Island College Hospital; Genitourinary Surgeon to the Long Island and Kings County Hospitals and the Polhemus Memorial Clinic; Member of Committee on Venereal Diseases in the Office of the Surgeon-General; Consulting Genitourinary Surgeon to the Flushing Hospital, to the Sea View Hospital of Department of Health, New York City, to the Bushwick Hospital, and to the Beth Israel Hospital of Newark, N. J.; Member of the American Association of Genitourinary Surgeons; Member of the American Urological Association; Fellow of the American College of Surgeons; Fellow of the New York Academy of Medicine, etc. Fourth Edition, Revised and enlarged, with 330 illustrations and 36 full-page colored plates. Price, $7.00. St. Louis: C. V. Mosby Company, 1918.

THE fourth edition of this popular work bears evidence throughout of its author's painstaking revision. Scarcely a chapter that is not infiltrated with at least minor changes and insertions. Chapters I and II on turbid urine and hematuria and IV and V on radiography and pyelography are new. Chapter III on tests of kidney function has been revised and modernized. The short chapter on complement-fixation test in the diagnosis of gonorrhea is new, likewise the contributions of Drs. Judd, Potter, and Burke on gonorrhea in women, the Wassermann reaction and the bacteriology of the gonococcus. The latter part of the volume is given to syphilis, and in this portion notable revisions and additions are found in those chapters on congenital syphilis, colloidal gold reaction, technique and accidents of intravenous arsenical injections and the intraspinous treatment of cerebrospinal syphilis. As in the preceding editions the author generously credits other workers in his literary references. His experiences and counsels are in harmony with contemporary urologists, and he continues to avoid any semblance to "faddism." In truth he gives consideration to a few of the old but now obsolescent methods and procedures, that might be more honored in the breach than in the observance. The volume is liberally illustrated, many of the cystoscopic plates being taken from Luys work on cystoscopy and urethroscopy.

LONG HEADS AND ROUND HEADS, or What's the Matter with Germany. By WILLIAM S. SADLER, M.D. Professor at the Postgraduate Medical School of Chicago; Director of the Chicago Therapeutic Institute; Fellow of the American Medical Association; Member of the American Association for the Advancement of Science, the American Public Health Association, etc., etc., etc. Author of "The Science of Living," "The Cause and Cure of Colds," "The Physiology of Faith and Fear," "Worry and Nervousness," "The Mother and Her Child," etc., etc. Illustrated. Price, $1.00 net. Chicago: A. C. McClurg & Co., 1918.

PROFESSOR SADLER, in company with many other philosophers, has been led astray by the fact that the great war just ended presented colossal qualities over-topping those of any other war simply because never before in the history of the world have there been so many people to fight, nor such resources of frightfulness. We do not believe it will profit much to theorize concerning the anthropological, psychological reasons, logical or illogical, for Germany's making war. Sadler's theory, briefly expressed, is that the present-day German is a mixture of Nordic egotism and Alpine stupidity. He has written an entertaining little book and his theory is an ingenious one, and his conclusion as to the middle European barbarian is a satisfactory one, however he arrives at it. His indictment of Germany is convincing.

TREBALLS DE LA SOCIETAT DE BIOLOGIA. Publicats sota la Direcció de A PI SUNER. Any V, 1917. Barcelona: Institut d'Estudis Catalans, 1918.

THIS volume of transactions, many of the articles in which are published in the Catalonian dialect of Spanish, is remarkable for a number of beautiful colored nucio-photographs and other forms of illustration. In a volume of Society transactions it is rare enough to see illustrations of any sort. Naturally a number of papers deal with histological subjects, especially methods of staining elastic fibers. Not a few papers deal with some aspect of anaphylaxis. As becomes a biological society the range of topics discussed is very wide. There are two case reports of action-dioplasic dwarfs and one of a mongoloid dwarf. Several papers were read by French colleagues—Vincent, Quinquaud, and others.

THE ACTION OF MUSCLES, INCLUDING MUSCLE REST AND MUSCLE RE-EDUCATION. By WILLIAM COLIN MACKENZIE, M.D., F.R.C.S., F.R.S. (Edin.), Member of the Council of the Anatomical Society of Great Britain and Ireland, and of the Staff of the Military Orthopedic Hospital, Shepherd's Bush, London; formerly Lecturer on Applied Anatomy to the University of Melbourne, and Examiner in Senior Anatomy to the Universities of Melbourne and Adelaide. With 94 Illustrations. Price $3.00. New York: Paul B. Hoeber, 1918.

NOW that great numbers of wounded men are returning from the battlefield with disabilities of an orthopedic nature, this book is particularly timely. At the same time it is unusually stimulating, and puts new life into what is often a dull piece of drudgery—the action of the muscles. The author studies this subject not from the textbook view point of "origin and insertion," but from the practical aspect of comparison of the function of given muscles in normal individuals and in paralytics. He also insists on the study of the action of muscles as compared with the action of their opponents. Those who are called upon to treat our returned soldiers will find this book of unusual value; and students will recognize the work as belonging to that very small class of books on anatomy which are really interesting.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Forty-sixth Annual Meeting, Held in Chicago, December 8, 9, 10, and 11, 1918.

THE PRESIDENT, DR. CHARLES J. HASTINGS OF TORONTO, ONTARIO, IN THE CHAIR.

The Etiology of Influenza.—Dr. WILLIAM H. PARK of New York City concluded that whether or not the bacillus of influenza was the initiating cause of the present epidemic, it gave evidence that it had a marked pathogenic action, and this seemed to be sufficient reason for them to make a thorough trial of an influenza bacillus vaccine on the prevention, if not of the pandemic, at least of a number of the cases of infection with this bacillus. The problem of producing immense quantities of vaccine, of determining the best dosage, the time for immunity, if any, to be established, of getting the proper controls in communities not yet infected, and, above all, of keeping good records and gathering and analyzing them was one of the most important and staggering of problems. They began with the use of influenza vaccine after the pandemic had already started, and some groups were not vaccinated until after the peak of the pandemic had been passed, so unless they had been able to get enough control cases—that is, presumably susceptible unvaccinated cases exposed to the same degree and observed at the same time as the vaccinated cases—they could arrive at no conclusions with regard to the efficiency of the vaccine. The reports from the use of the vaccine were being analyzed now, and it was already apparent that the majority of them were lacking in many essentials. The intelligent use of the vaccine might have given them strong evidence in regard to the etiological relationship of the influenza bacillus to the present pandemic. As it was, unless the finished reports proved to be better than they now promised, they must wait for such evidence as might be gathered from a serological study of the various strains of the influenza bacillus isolated by them from the typical cases and from control cases.

Dr. E. O. JORDAN of Chicago stated that in the present outbreak of influenza conditions had been very different from those of which he had record, and instead of 8 or 9 per cent. of the deaths occurring between the ages of twenty and forty, over 60 per cent. had been between the ages of twenty and forty. Where we found a similar bacteriological picture in the true respiratory tract infections, it seemed fair to suppose that neither the Pfeiffer's bacillus, the pneumococcus, nor the various varieties of streptococci were responsible alone for these outbreaks. We had in cases of pandemic influenza an infection with an unknown or unrecognized virus which increased the susceptibility of the individual normally to infection with the various pathogenic respiratory tract organisms, and superimposed on the initial infection we had a variety of secondary infections.

Dr. J. W. NUZUM of Chicago said that, as regards the use of vaccines in influenza, he had seen some cases of the disease developing after the first injection of the vaccine, and he knew of instances occurring after three injections of the vaccine, but he did not care to venture an opinion until he had been able to do considerable control work. He had been impressed with the frequency of empyema in these cases. In the wards at the Cook County Hospital they had had from 50 to 100 cases with empyema, and the predominating organism was the hemolytic streptococcus, a late secondary invader.

Dr. WILLIAM H. STOKES of Baltimore said that he had found the streptococcus and the pneumococcus, types II and IV, and in about 10 per cent. of the cases, both at autopsy and in the sputum, they found the influenza bacillus.

Lieut.-Col. JAMES G. CUMMING of Washington, D. C., stated that in a series of 100 specimens he had found only 12.4 per cent. of influenza bacilli. In 27.6 per cent. he had found the hemolytic streptococcus, in 90 per cent. Group 4 pneumococci. He had found a low percentage of the fixed types of pneumococci. He had likewise found about 20 per cent. of micrococcus catarrhalis and a few staphylococci.

Dr. LUDWIG HEKTOEN of Chicago thought we must be dealing with a disease of unknown etiology, complicated by secondary infections of different kinds, depending upon local conditions in different parts of the country.

Dr. M. J. ROSENAU of Boston stated that in the first twenty-six or more autopsies he recovered the influenza bacillus as the organism described by Pfeiffer in 83 per cent. of the cases examined. He also found it in pure cultures of the lungs of the fatal cases in a number of instances. In the remaining 17 per cent. of fatal pneumococcic cases he failed to find the influenza bacillus. These patients died of croupous pneumonia due to types II and IV of the pneumococcus, and in a few instances of the hemolytic streptococcus.

Dr. WILLIAM G. WOODWARD of Boston asked what had been the prevalence of the various kinds and strains of streptococci and pneumococci in the civil population prior to the appearance of influenza, and what had been the relative prevalence of these particular organisms among groups of persons in infected communities who had not had the disease?

Dr. WILLIAM E. PARK of Rockford, Illinois, stated that, so far as vaccine was concerned, he had not used it in cases of influenza. The Government had been using a lipovaccine and had given it to several thousand civilian employees, and, as far as he knew, no case of influenza had resulted from taking the lipovaccine. He gave the vaccine for three days for pneumonia cases and no cases had developed.

Dr. WILLIAM D. STOVALL of Madison, Wisconsin, said that unless a vaccine was made by growing the type in pure culture and mixing the type according to the organism present, a vaccine of definite value could not probably be obtained, because the media favorable to the growth of the pneumococcus could not be favorable for everything. One type might overgrow the other. If they were grown in pure culture one might get definite effects from each type.

Dr. H. W. HILL of St. Paul, Minnesota, said that there was a very prevalent belief among a great many people that relatively few cases of tuberculosis had escaped influenza. He would like to know the experience of the members in regard to tuberculosis and influenza.

Dr. J. O. COBB, United States Public Health Service, Chicago, stated that at Fort Stanton, New Mexico, they had had a very decided outbreak of influenza, with 149 cases out of 300 tuberculous patients, with 18 per cent. of deaths. The cases were identical with our present epidemic and the patients died just as promptly at the Government sanatoria there as they did elsewhere.

Dr. PARK, in closing, said that in the East there had been very little influenza complicated by empyema, but in different parts of the country there had been important and different secondary complicating organisms. In the hospitals in the East they had only had one case of empyema in some sixty deaths. As to the prevalence of the influenza bacillus in the cases prior to this outbreak over other organisms, he would say the influenza bacillus had been present in the East in a great many cases in this epidemic, and undoubtedly every case of whooping cough had the influenza bacillus.

Prophylactic Inoculation in Pneumonia and Influenza.—Dr. EDWARD C. ROSENOW of Rochester, Minnesota, said that by the use of a properly prepared vaccine it was possible to afford a definite degree of protection, particularly in pregnant women, during an epidemic of influenza; there was no noticeable increase in the number of cases immediately following the inoculations, and protection lasted for a period of at least six weeks. The favorable results from inoculations indicated that the socalled secondary invaders which appeared to have exalted and peculiar infecting powers bore a close etiological relation to epidemic influenza. This relation, however, might be in merely favoring the invasion of an unknown virus. Nearly all physicians reported that the attacks of influenza were milder, of shorter duration, and convalescence more rapid in inoculated patients as compared with uninoculated individuals. The tendency to infection of the lower respiratory tract to develop pneumonia was noticeably less in the inoculated. The prophylactic vaccinations had conferred, according to the evidence

at hand, a decided immunity in pregnant women. This infection had proven so very fatal among the uninoculated of this class.

Dr. GEORGE W. McCOY of Washington, D. C., stated that in one institution where there were approximately 2 300 people they had sufficient vaccine for 500, excluding from consideration every one in the institution above the age of forty-one; but below the age of forty-one they went through every ward, they selected each alternate patient, making 400 patients. The vaccination was finished on November 15. These people were given three doses at intervals of forty-eight hours, running for a period of five days, beginning with Monday and ending on Friday. On November 15, almost providentially, no influenza appeared in that institution, and did not until November 26, eleven days after the vaccination had been done. When the disease did appear, it was a source of great regret to all of them who had anything to do with the work. The vaccine failed to protect anybody. He paid his last visit to the institution on December 4. Up to that time, among the 400 that had been vaccinated, there had been sixty-four cases of influenza and two deaths. Among the 400 unvaccinated, those below the age of forty-one, there were sixty-four cases. It was remarkable that the number was the same.

Dr. TIMOTHY LEARY of Boston said that in the treatment of influenza with an autogenous vaccine grown on human blood agar, he started on a local piece of work with first some students and nurses in certain institutions which were receiving the first cases of influenza, and in which the incidence and mortality were very high. The results indicated definite value, and he proceeded from that to offer the vaccine for immunization to doctors and nurses generally. Again the reports came back distinctly favorable, and if the agent was of definite value it seemed to him that its use should be spread. He had as yet no definite information on which to draw final conclusions.

Dr. F. O. TONNEY of Chicago said the ratio of influenza cases developing pneumonia in the unvaccinated of industrial groups studied was 1 in 21, while in the vaccinated it was 1 in 184. The ratio of influenza cases terminating fatally in the unvaccinated of the industrial groups in Chicago was 1 in 408, and in the vaccinated there were none in the 1,201 reported cases completely vaccinated. The influenza in vaccinated individuals occurred almost exclusively in those who had received one vaccination. No bronchopneumonias or deaths occurred in the vaccinated group after the second or third vaccination. The number of severe local reactions following vaccination was at the rate of three per 1,000, and of severe constitutional reactions at the rate of two per 1,000. These results were incomplete, but he offered them for what they might be worth.

Dr. J. J. MOORE of Chicago stated that he had found hemolytic streptococci in the sputum, bronchi, lungs, and especially, as Dr. Nuzum had said, from the pleural complications of this disease.

Dr. W. O. SHERMAN of Pittsburgh said that at the Homestead plant there were 1,687 employees who were not inoculated; 588 of those contracted the disease, or 30 per cent.; the number of deaths was 42, a percentage of 2.5. There were 5,964 who received one inoculation; of these 213, or 3.5 per cent., developed the disease; there were 9 deaths among these, or a percentage of 1.5. Of 5,222 who received two inoculations 174 developed the disease, or a percentage of 3.2, with 4 deaths; the death rate was .08. There were 4,720 who received three inoculations; 66 of these contracted the disease, or a percentage of 1.4; no deaths in those with three inoculations. There were 4,007 who received four inoculations at the one plant and this data was accurate; 108 contracted the disease, or a percentage of 2.8, with 2 deaths, or a death rate percentage of 1.05.

Admiral E. R. STITT of Washington, D. C., stated that they had been successful at the Naval Hospital, as they had in Boston, in treating post-influenzal pneumonias with the serum of convalescents, and a very interesting thing in connection with trying out the serum of some of the convalescents was the potency of the serum therapeutically. It seemed to be almost a specific. He had the laboratory workers in the Naval School try out immunity reactions with this potent serum, which he knew was potent from treating different cases, and they were unable to find that the various strains of influenza bacilli had any more agglutinating power over the serum that was not therapeutically efficient. There was no evidence that this serum possessed any antibodies of various strains of influenza bacilli.

Colonel VICTOR C. VAUGHAN of Washington, D. C., said that as regards pneumonia, the army had a splendid record for the first six months of the war. It had a death rate but little above that of the same age group at home, and thirteen out of the twenty-nine large cantonments had a death rate lower than the same group at home. So far as pneumonia was concerned, during the first six months these facts seemed to have been established: the city boy lived, the country boy died; the northern boy lived, the southern boy died. It had been almost impossible for them to study influenza, because men had been dying from pneumonia in great numbers, and they could not spend the time to examine the blood of patients with influenza when so many of them were dying from pneumonia. We were going to have influenza with us; it was not going to disappear very soon. So far as the prevention of the respiratory disease was concerned, we did not know any more than our ancestors did a hundred years ago. He had used influenza vaccines and lipovaccines, and from data gathered they had not done one bit of good.

Dr. B. FRANKLIN ROYER of Harrisburg, Pa., said that his experience had been that there was no dependable data so far relative to the value of vaccines so that their use could be recommended. He could mention a dozen communities as examples where the epidemic of influenza was apparently snuffed out just as efficiently with the measures they used as in those of communities where the vaccine was used.

Dr. G. H. WOOD of Detroit, stated that there had been some very severe reactions, some marked depressing effects from the use of vaccine in influenza. A safe rule to follow was not to give more than one-half of the dose recommended at the beginning, then watch the patient, and increase the dose as the results warranted.

Dr. ROSENOW, in closing, said that we could not solve the problem of influenza or any other problem regarding the management of disease unless we tried out experimentally certain methods. He had watched the occurrence of this disease through his section of the country, and for him to sit down quietly and do nothing was impossible. He stopped very vital work of other kinds to try and do something for his countrymen.

Organization of Forces Against Influenza.—Dr. M. NICOLL, JR., of New York City stated that the general mortality caused by this unknown disease had never been equalled in the country as a whole. This unknown disease killed by secondary pneumonia, usually of a peculiar bronchopneumonic type and due to a variety of organisms, including probably the socalled influenza bacillus. The uncomplicated disease caused a marked leucopenia, together with a profound toxemia, with a tendency toward the production of hemorrhage. The age of special susceptibility was that of young adult life. Among pregnant women it was especially fatal. Those who went to bed and remained there, even with ordinary nursing care, until at least a week after the establishment of full convalescence, would in the large majority of cases recover. Strict quarantine of groups of people had been successful in keeping out the disease.

Dr. WILLIAM C. WOODWARD of Boston said that the following measures had been adopted for the prevention and spread of influenza: Reporting of the disease; the use of masks, the use of vaccine; hospitalization; regulation of the use of common drinking cups in restaurants, lunch-rooms, etc.; restriction of crowding; education. Reporting the disease gave a clue to its prevalence in times of epidemic and served as a guide in taking measures for the prevention of the disease.

Dr. W. O. SHERMAN of Pittsburgh believed that there was sufficient evidence at hand to warrant us in believing that from a prophylactic standpoint there was some virtue in the use of vaccines in reducing the severity of influenza.

Dr. JOHN DILL ROBERTSON of Chicago stated that many

places of amusement were closed during the epidemic of influenza to give the people of Chicago more sleep. He believed sleep was the greatest regenerating agent known to mankind. The better class of theaters were not closed because in them ventilation was good, and such places were used as centers of education for instructing the public regarding the epidemic.

Dr. H. O. JONES of Chicago said the consensus of opinion was in favor of keeping the public schools open during an epidemic of influenza for the following reasons: A better knowledge of existing conditions could be had when the schools were made a source of information as to sickness among the children and their families. It would be possible to supervise the children and keep many of them under better conditions during the school hours than if they were allowed to stay at home and run in streets and alleys, or play on premises where persons sick with the disease lived. They had an organized staff of physicians and nurses for medical inspection of schools.

Dr. ROYAL S. COPELAND of New York City stated that in the New York epidemic any children found with running noses or coughing, or with any symptoms which indicated the possibility of influenza, were put in a room until examined by a nurse or doctor to discover whether or not they had the disease, and if they were found to have the disease they were sent home under the care of the Board of Health, and a Board of Health doctor or nurse found out the name of the family physician and determined whether there was a possibility of isolation and protection of other members of the family. If the family had no particular physician or could not afford one, the child was cared for in a hospital. This measure was found very effective in preventing the spread of the disease.

The Rôle of the Hand in the Distribution of Influenza.—Col. CHARLES LYNCH and Lieut.-Col. JAMES G. CUMMING of Washington, D. C., drew the following conclusions: "(1) The casual organisms of sputum-borne diseases, resident in the mouth and nose, leave the body of the infected through these orifices and enter the non-infected through similar channels. (2) The vehicles for the transfer of germ-laden saliva from, and to, the mouth and nose are the hands and eating utensils. (3) Crowd diseases have their origin, to a large extent, in the constant accumulative contamination of intermediate objects, which are the distributing centers of the infection for many hands and many mouths. (4) Food may be infected by contaminated hands and then spread the sputum-borne infections, as well as the intestinal-borne infections. (5) In all infectious diseases there are major and minor routes of transmission from the sick to the well. In military life the mess-kit, wash water has proved to be the major route, intermediate object conveyors by hand touch the minor route. Droplet infection is subsidiary to both, because explosive outbreaks do not result from droplet infection, and as far as mouth pathogens are concerned, 18 in. is about the maximum distance that plates on a level with the mouth can be infected by droplets expelled through the act of coughing. Moreover, since the weight of these droplets (even the finest spray) is such that they fall rapidly, the probability of infection by the flight of organisms is remote. (6) It is true that the chain of both direct and indirect transmission may be broken in several ways; one of these is by wearing the mask. This acts in two ways: It prevents droplets being expelled from the mouth and it also prevents the hands being put in the mouth. On this basis the value of the face mask may be emphasized. It value, however, lies in the fact that it serves as a barrier between the hand and the mouth rather than between the mouth and the outside air. The relative importance of this face mask to clean hands is just about the same as in the case of the surgeon who would wear a mask but neglect to wash his hands. In order for the mask to be effective the wearer must wash his hands before it is removed. Was there a lower rate of infection in cities where the populace wore masks as required by the local ordinance? According to the United States Public Health reports in San Francisco, the wearing of masks was required; the rate per 1000 was 4.6 for seven weeks; in New York masks were not worn and the rate was 4.7 for eleven weeks. (7) Very probably droplet infection, when it does occur, is indirect, rather than direct, that is to say, mouth spray does not immediately reach the mouth of another person, but reaches the hands and intermediate objects from which germ-laden saliva is picked up and carried by the hand to the mouth of the non-infected. (8) In the prevention of sputum-borne epidemics, the hygiene of the hand and the hygiene of eating utensils is of paramount importance; clean hands, disinfected eating utensils, the avoidance of intermediate object conveyors handled by many persons, the frequent cleansing of such conveyors, the keeping of the hands away from the mouth and nose, and elimination of the sick from the kitchen, these are the essentials of such prevention." But above all was the necessity for popularizing our knowledge that it was the sputum-soiled hands, and the contaminated eating utensils which played the chief rôle in the mouth-to-mouth infections.

Dr. W. H. KELLOGG of San Francisco stated that gauze masks were given a thorough trial by an ordinance enforcing their use in San Francisco. Beginning with the use of these masks there was a rapid decline in the number of cases of influenza. The experience of Los Angeles had proved that the wearing of masks was a great preventive of the disease. In that city, where they did not use masks, they had a much larger number of cases of influenza than in San Francisco. A properly made mask afforded efficient protection against droplet-borne infections.

Dr. WOODS HUTCHINSON of New York City said that the San Francisco people were asked to wear masks in the interest of public health and for public safety. They co-operated with the public health authorities in this regard with the result that there was a great reduction in the number of cases of influenza.

Dr. A. J. MCLAUGHLIN of Washington, D. C., said that until we had exact knowledge of the etiology and transmission of influenza we would not be able by laboratory methods to develop biologic agencies or products for the prophylaxis and therapeutics of the diseases. Quarantine measures and the wearing of masks were a protection to individuals.

Dr. LOUIS I. HARRIS of New York City said that the reorganization of the various health forces of the country for future emergencies and for protecting and caring for recrudescent cases of influenza was very essential. There should be adequate appropriations of money by federal, by city and State organizations, so that the work of prevention and treatment could be carried out on a scale commensurate with the importance of the problem.

The Work of the Illinois Influenza Commission.—Dr. C. ST. CLAIR DRAKE of Springfield, Ill., stated that from the onset of the epidemic up to and including November 30 reasonably active reports from 1348 Illinois health jurisdictions, within which was embraced 60 per cent. of the total population of the State, showed 193,885 reported cases of pneumonia and influenza, 53,000 of which were in Chicago. In the same areas the reported deaths numbered 13,466, of which 9,129 occurred in Chicago. It was found that no preventive vaccine had been used in twenty-one counties and that it had been employed only to a moderate extent in seventy-two counties. Only four counties in the State claimed its general employment. In addition to the vaccine furnished by the Illinois Influenza Commission and the Chicago Health Department, ten others were employed. As to whether or not these vaccines had served to prevent the spread of infection, nineteen counties offered no definite opinion, twenty-nine answered in the affirmative, twenty-seven were of divided opinion and sixteen regarded the vaccines as of no preventive value. Regardless of definite opinions as to the general value of vaccines, based upon the experiences of these counties, the following figures were gleaned from these very interesting but highly unreliable questionnaires: Counties in which there were no cases after vaccination, 23; counties claiming partial protection, 7; counties in which the severity of the disease was decreased by vaccination, 21; counties claiming prevention of pneumonia, but not of influenza by vaccination, 1; counties reporting influenza after vaccination, 24; counties claiming pneumonia after vaccination, 4; counties claiming deaths after vaccination, 4; counties claiming absolutely no pre-

ventive value, 4; counties claiming disease increased by vaccination, 2.

Dr. Owen J. Mink of the Great Lakes Naval Training Station, Illinois, stated that early in the epidemic, in military camps of 40,000 to 50,000 men, influenza followed a very typical curve in its incidence and a typical curve in its death rate. When the influenza arrived at the station the incidence increased with explosive violence for about five days. After four or five days it reached the peak, and after that it began to decline. In two weeks the epidemic began and practically ended. Of 1000 men in a regiment before the epidemic was over, between 200 and 300 men contracted the disease. One tent camp had an incidence of 300 per 1000; another camp composed of barracks had an incidence of a little over 200. A member of the hospital corps kept track of those who wore masks and of those who did not. Of those who wore masks 8 per cent, developed influenza. Of those who did not use masks 7¾ per cent. developed influenza. The use of the masks seemed to have very little influence upon the incidence of the disease. At the station there were two distinct types of influenza, winter influenza and a severe type of the disease accompanied by pneumonia.

Report of the Committee on Administration for Relief During the Influenza Epidemic.—Dr. William C. Woodward of Boston said that the committee was charged with the formulation of certain principles for the guidance of health officers in communities for administrative measures and for the relief of epidemic conditions with special reference to influenza. Under general rules the committee suggested compulsory reporting of cases in so far as it enabled the relief measures to be directed to particular cases that might be reported, and in mentioning compulsory reporting they referred to the matter of isolation and placarding, calling attention to the fact that in so far as isolation was compulsory it might lead to a diminished efficiency in reporting, so that while the committee recommended isolation by co-operation and education, it recommended that it be carried to a point where it did not diminish the willingness of the physician to report, and the principle held true with respect to placarding. Under preliminary measures the committee recommended the distribution of resources, including physicians, nurses, social workers, nurses' aids, clerks, domestics, laundresses, automobiles, and volunteers of all kinds. The local authorities should keep in touch with State and national agencies.

Report of the Committee on Bacteriology and Vaccines.—Dr. William Hallock Park of New York stated that the committee reported that the epidemic disease known as influenza was believed to be due to an undetermined organism which caused an infection that lowered the resistance of the body as a whole and of the respiratory organs in particular. This allowed the invasion of other pathogenic organisms. The most important complicating infections were due to influenza bacilli, different strains of pneumococci, different strains of streptococci, etc. In each case one or several microorganisms might be present. In different portions of the country a dominating variety or organism had been found to differ. Assuming that the cause of the epidemic was an unknown virus, it did not seem possible at present to prevent the primary disease by vaccination with known organisms. Against the secondary infections there would seem to be theoretical basis for the use of vaccines prepared from organisms responsible for the complications which might develop in various localities at various times.

Dr. James W. Inches of Detroit said the wearing of masks by the laity on the streets and in public places was of doubtful value. He regarded the wearing of masks on the streets as a pure fake. Detroit was closed up for sixteen days during the epidemic. When the theaters and other places were closed in Detroit it deprived the Board of Health of the opportunity of affording the people education in regard to the epidemic. When everything was wide open the number of cases of influenza was less.

Dr. W. L. Holt of Beloit, Wis., protested against the wholesale condemnation of the gauze mask. The mask should be made of six to eight thicknesses of gauze. Such a mask would prevent droplet infection. Scientific experiments showed that it was impossible for the pneumococcus to go through six or eight layers of gauze.

Dr. James A. Hayne of Columbia, S. C., said that on receiving a telegram from Surgeon-General Blue regarding the pandemic of influenza, the State health officers of Virginia, North Carolina, South Carolina, and Georgia held a conference and issued simultaneously an order for closing, so that every single school, church, theater, moving picture show, etc., was closed, and the closing of these places materially lessened the number of cases of influenza and the death rate. When people assembled in large crowds there was certainly a greater conveyance of droplet infection than if they did not. Eighty per cent. of the population of America was rural, and it was no easy proposition to formulate rules and regulations for the different rural communities. He heartily approved of closing in times of epidemic.

Dr. Roy K. Flanagan of Richmond, Va., stated that the schools were closed in Richmond, but what was accomplished by it he did not know. The results in Richmond compared favorably with other cities in regard to death rate. The death rate was lower in Richmond than in most cities on the Atlantic seaboard. It was 3.8 per cent. in August per 1000, and 4.2 per cent. per 1000 of deaths in the months of September, October, November. There was an epidemic prevailing at present, but the second exacerbation was milder.

Dr. E. B. Oliver of Fort William, Ontario, favored the keeping open of public places, such as theaters and churches, but was overruled. Then the people crowded into the five and ten cent stores with the result that there was a large increase in the number of cases of influenza.

Dr. Charles V. Craster of Newark, N. J., stated that the association should be slow in condemning the use of the gauze mask because its value had been demonstrated in many instances in preventing bacteria from entering the upper respiratory tract. It was advisable to stop persons from crowding together. Droplet infection was minimized by keeping people apart as much as possible. Rational closing measures should be adopted when epidemic diseases prevailed.

Dr. J. O. Cobb, U. S. P. H. S., said that Dr. Hayne was right inasmuch as there must be rules and regulations for the health officer in the sparsely settled municipalities and communities, but cities like New York, Chicago, Detroit, must have some other methods of dealing with the public during a terrible scourge like influenza. The problem must be looked at purely from what one could do and not what might be ideal. One could do in Chicago what he could not do in South Carolina. The prevention of the spread of influenza could be controlled by a properly made and worn mask. The schools should be kept open in all large cities and business allowed to go on as usual.

Dr. Thomas E. Maloney of Fall River, Mass., asked did closing close? Did masks mask? He was prompted to ask these questions after the important statement made by Colonel Vaughan that influenza was a hand to mouth disease. So far as he had observed, in many of the rural communities in New England the incidence of the disease was much greater in rural than in industrial communities.

Dr. Elias Pratt of Torrington, Conn., asked if the disease was transmitted by crowding. One gentleman said that he had closed everything in his city, and then the people went into the five and ten cent stores, crowded together, and in that way spread the disease. Did crowding help to transmit the disease? On the decision of that question would rest the action that health officers should take. If crowding did not transmit the disease or spread it, it was foolishness to stop crowding. He believed that vaccines were of value from his experience in vaccinating factory employees.

Dr. W. E. Moore of Sioux Falls, S. D., said that when the epidemic started in his city they closed up everything for seven weeks, and when they opened wide they had an explosion of the disease, and now they were having more cases than ever. He advised the use of masks for nurses and others who were brought into contact with patients suffering from influenza. An important question was, how long would the disease last? Schools and theaters could not be closed forever.

Dr. E. H. Willard of St. Joseph, Mo., stated that they had been closing picture shows and other places with a view to preventing the spread of the disease, and yet it had kept on increasing and was becoming more and more prevalent. He hoped the association would map out a definite program for limiting the spread of the disease and of treating it, if possible.

Dr. William R. Stokes of Baltimore said that the face mask was a good thing. It was said that the physicians during the epidemic in Manchuria who wore masks did not contract pneumonic plague, and those who did not use the mask had the plague. The mask should be made of three or four layers of butter cloth. The pneumococcus was able to pass through the ordinary mask.

Dr. J. L. Folston of South Dakota agreed with Dr. Inches. After the influenza began he secured a supply of the Rosenow vaccine from the Mayo Foundation, and with the free use of this vaccine he had lost only one patient. In regard to the mask, he had told his people not to wear them. He believed that masks were just as filthy a thing as a big mustache.

Dr. William W. McDonald of Jacksonville, Fla., stated that the influenza appeared in Jacksonville about the 8th of September. At first the cases were mild, with a simple rash on the chest. About one-third of the population in Jacksonville was susceptible to influenza. He had definite records of 17,000 cases, which was one-half of the number of cases they had had. In October they lost 450 cases from the complications of influenza. They closed up everything at the end of the first week in October and kept closed until the epidemic was over. The population of Jacksonville was approximately 120,000, and the death rate in the month of October from influenza was 71.5 per cent.

Dr. H. Delamater of St. Joseph, Mo., said the first case of influenza in St. Joseph came from the Great Lakes on September 15. They realized that influenza was a contact disease. The cases were isolated from the start. The use of masks was not advocated. The masks had been abused and damned by many members. If the mask was condemned for influenza, then why not condemn it in cases of diphtheria, scarlet fever, and so on?

Major C. H. Clark of Rock Island, Ill., stated that it was not known definitely whether the disease was air borne or not. If one followed the epidemic from any Army standpoint at the camps, he would find that in the first week the disease increased rapidly, the next week it took a boom, and at the close of the second week it declined so rapidly that it was practically over in two weeks. It was established that influenza was a contact disease. He did not think that closing the schools had any effect on the spread of the disease. At Rock Island the people were advised to go to bed the very minute they showed the first signs of the disease, and the people who had the disease and followed this advice had very mild attacks. The prevention of crowding was a good thing. He did not believe in wildfire closing down.

Colonel Cumming of Newport News, Va., believed in the value of the mask. It acted as a barrier between the hand and mouth rather than between the mouth and the outside air. Influenza as a crowding disease was a misnomer. Where individuals had gathered together in large crowds for the purpose of commercial exchange or theater parties the incidence of the disease had not markedly increased, but when people gathered together in large crowds for the purpose of eating there was generally an explosive outbreak.

Dr. Frederick Montizambert of Montreal believed in the use of the masks for nurses and others who came in contact with the sick. After the mask had been used for a certain time the circle opposite the mouth became moist and moist surfaces would not receive droplet infection. The droplets would not dry off and consequently they were sucked into the moist surfaces and protection was not afforded. A dry mask would stop droplet infection. Masks should be frequently changed. Another point in connection with the wearing of the mask was the possibility of infection from the conjunctiva. It was not sufficient to protect the nostrils and mouth, and nurses and others in influenza cases were exposed to droplet infection and should wear masks with transparent eye pieces.

Dr. R. M. Olin of Lansing, Mich., thought the association should not condemn anything until it knew what it was dealing with. It was important to determine some means of checking this epidemic, and until we knew how the disease was transmitted and the nature of it, we were not going to arrive at any conclusions that were justifiable. He would not condemn the use of the mask, although he had not advised it in Michigan.

Dr. John Dill Robertson of Chicago said that the association should take the position that the disease was transmitted by the air and by droplet infection. He advocated wearing the mask inasmuch as it was effective in contagious disease hospitals. It was better to take a middle ground in considering this important problem and try to embrace everything that was good.

Dr. A. W. Carnes of Dallas, Tex., was opposed to the closing of public schools, churches, and so on. The medical profession recognized the fact that child life was not the age or even school life was not the age most susceptible to influenza, but the age most susceptible was the age of those working in department stores and in office buildings and thus spreading the disease by contact. As a means of preventing the spread of the disease, it was better to close those buildings before closing schools and churches. He argued that if the schools and churches were closed, the five and ten cent stores and all business activities should be closed. When these were closed crowding would stop. Should every man and woman be sent home and business activities stopped? If so, how long were these places to be closed? Restaurants were a cause of the contagion and on general principles such places should be closed also.

Dr. Milbank Johnson of Los Angeles said he would like to speak of frequent hand-shaking in America as a possible factor in conveying the disease. Americans could profit by the custom of the Chinese to shake their own hands as a greeting rather than those of others. If influenza was a contact disease, it made no difference what kind of a microorganism was causing the trouble; doubtless the shaking of hands was a factor in causing its spread and a method of conveying respiratory diseases. He would urge the members to follow the Chinese custom and see if there was anything in it; it did not cost anything.

Treatment of Influenzal Pneumonia with Plasma of Convalescent Patients.—Lieut. Frank W. Hartmann, U. S. Navy, stated that in the present epidemic the Medical Department of the Navy had been treating not only the officers and their families and the enlisted personnel, but also all civilian employees. Up to December 6, 523 cases of influenza and complicating pneumonias were treated at the Naval Hospital. Of these 27.5 per cent. either came in with pneumonia or developed it during their residence. The outstanding feature was an overwhelming toxemia, characterized by headache, muscular fatigue and pain, mental depression and dullness, leukopenia and, in many cases, by nausea and vomiting, and the cases failed to respond to ordinary therapeutic measures, especially when pneumonia complicated the disease. He believed two factors aided in keeping the mortality percentage low in the first days of the epidemic—digitalis and venesection. Isotonic glucose and sodium bicarbonate intravenously and massive doses of camphorated oil were each given in a series of cases without beneficial results. In the later stages venesection was most efficacious in combating dilatation of the heart and flooding of the lungs. Blood was drawn with a needle into a sterile eight ounce nursing bottle so cultures could be made in every case. Pfeiffer's bacillus was grown repeatedly from sputum, lung puncture, and autopsy material, but never from the blood stream. At the height of the epidemic a suggestion came from the Chelsea Hospital, Boston, that the serum from convalescent patients might be of curative value, and he determined to give the method a trial. The following were his conclusions: "(1) The toxemia of influenza seems to be neutralized by the plasma from convalescent patients. (2) Certain care being exercised tests for compatibility are eliminated. (3) A large percentage of all plasma is active, and most satisfactory results are obtained by pooling the different lots. (4) Sharp reactions are followed by the most prompt

improvement, but are not essential to success. (5) Pneumonia must be diagnosed early and treated immediately if a high percentage of cures are obtained. (6) Mortality percentage has been reduced from 25.2 to 6.5 per cent., treating every case."

Dr. S. PIETROWICZ of Chicago said that his experience had been limited to several hundred cases seen at the Cook County and St. Mary's Hospitals, but he believed there was an era of awakening regarding this form of treatment for respiratory diseases. Many physicians still suffered with airophobia and kept their patients in hot rooms, but at the Cook County Hospital the first thing done was to place the patients in rooms with open windows, keeping them well covered, and they had found that fresh air was the cornerstone of therapy. Even patients who were cyanotic were greatly benefited almost immediately by this treatment. This had convinced them that fresh air had certain specific properties. First, it was a tonic, then a sedative, a stimulant, and an antipyretic. He was sure that its chemical value, its physical value, its respiratory and cutaneous value could not be overestimated, and this method of treatment should be used more extensively. The contraindications for this treatment were very few—old age, extreme youth, and patients with profuse hemoptysis.

Dr. A. A. GOLDSMITH of Chicago said he had been under the impression that every man had a different treatment for influenza and pneumonia, and yet got practically the same results, except perhaps at the Great Lakes and other cantonments, where the mortality was very high. He thought certain of the cases were doomed from the start and no treatment, unless perhaps the serum, was of any value. He believed in the fresh-air treatment and quiet conditions, and thought that aside from these one had very little power over the course of the disease, and that just as many patients were killed by physicians as were cured by them. Often patients were continuously stimulated and went on to a fatal termination when, if they had been left alone, many would have recovered. During the last ten years he had tried to leave his patients alone, allowing them to rest as much as possible, giving codeine for the cough, if it was necessary, and occasionally morphine, but not bothering about the stimulation. If the toxemia could be combated, that was all that was necessary, and if patients were kept quiet and allowed to sleep the mortality would be lowered.

Dr. H. N. BUNDESON of Chicago believed that the serum treatment of pneumonia and influenza was of great value, just as like procedures had given similar results in scarlet fever and diphtheria. From the reports of various workers it appeared to be almost a specific. The doses should be large, 200 c.c. of convalescent serum given very slowly over half or three-quarters of an hour's time. If there was not a quick drop in the temperature within a short time, another 200 c.c. should be injected. He believed one cause of failure in this treatment was that patients coming from one part of the country were injected with serum from a man from another part of the country and the serum was probably of a different type. The best results could be obtained from the same type of serum in the same hospital. He believed the serum treatment was efficient only when given early, as was also true of the antidiphtheritic serum.

Dr. B. S. MALOY of Melbourne, Fla., stated that he had treated 225 cases of influenza and pneumonia in the recent epidemic and had not lost a patient. On his first visit to the patient he gave tincture of aconite and tincture of veratrum viride together. This should be continued in half teaspoonful doses every half hour until six to ten doses had been given. At the same time he gave the patient 2 or 2½ grains of calomel in one-fourth grain doses, crushing the tablets and mixing with a little water. Six or eight hours after the last tablet had been given he gave one or two heaping tablespoonfuls of epsom salts. His experience had shown that this treatment would abort pneumonia in many instances. He believed these patients should be given as little medicine as possible. He gave no opiate or anodyne for the pain, and nothing for the cough until the temperature had subsided. On the first indication of a failing pulse or the slightest trace of cyanosis, the best brandy or whiskey obtainable was given in teaspoonful doses every three hours, and when necessary, increasing to a tablespoonful dose every hour. He did not believe in the use of jackets, oils, and similar things, and thought the patient should not be interfered with until he was well on the road to recovery. Hot, rich soups and broths should be given and plenty of butter, but no milk. During convalescence a good tonic was of value.

Dr. JOHN DILL ROBERTSON of Chicago was of the opinion that the treatment suggested by Dr. Maloy would bring better results than anything else. It was old-fashioned treatment and was being used with excellent results by many physicians in the present epidemic. To give opiates of any kind was to invite pneumonia.

Lieut. L. R. MELNIKOFF of the Great Lakes Naval Training Station, Illinois, said that the conclusion at the base hospital at the Great Lakes was that the so-called wonderful cures that had been reported outside of the Army and Navy camps had not been cures of influenzal pneumonia, but of straight influenza or acute cold. On the post-mortem table there was no normal tissue left in the lungs in the cases of influenzal pneumonia. The serum treatment had been tried early in the epidemic with very little success, but it was not the same method as that used by Dr. Hartmann. Venesection could not be successfully done because the circulation in the cases was practically nil and the blood clotted too rapidly. Pneumonia cases did better in the hospital units than those in tents and most cases were treated in that way. Calomel and salts were given, and in the early cases some aspirin, but this was soon discontinued, as it was found to be a depressant. If the pulse was over 100, 15 minims of digitalis were given every three hours. Codeine was given in very small doses for cough and fluid was given frequently, but very little catharsis was employed. Whiskey should very seldom be given except as nourishment. Of 3,000 cases at the base hospital 20 to 30 per cent. developed pneumonia, and of these about 20 per cent. resulted fatally.

Dr. JAMES S. BOYERS of Decatur, Ind., stated that his experience had been the same as Dr. Maloy's, and he felt that his treatment was correct. If a patient was aching he would suggest the addition of salicylate of soda and two drops of carbolic acid be added to the mixture, which would relieve the bloating of the intestinal tract beyond the stomach. This combination produced a salol which was not absorbed by the stomach. We must not forget that influenza bacilli developed more readily in an acid medium, and the first thing to do was to render the stomach alkaline.

Dr. A. C. TENNEY of Chicago mentioned a modification of the vaccine treatment as a preventive measure, thinking that the members might be interested in the results of several years' experimentation and observation, checked by laboratory tests. The idea was simply to furnish an excess of nucleinic acid in the region where the vaccine was introduced. The tissues must be thoroughly massaged after the hypodermics were given. The vaccine selected was introduced in the usual manner, and centrally from that point a dose of nucleinic acid was introduced. He recommended this procedure to those who wished to prevent pneumonia and influenza or a mixed infection from which so many people were suffering. Veratrum viride was not a new remedy. Four years ago it was shown to increase the opsonic index, and this drug in connection with urotropin had been his mainstay in the treatment of the present epidemic.

(*To be continued.*)

Leprosy in Brazil.—Figueria de Mello in a monograph recently published on leprosy and its prophylaxis states that the number of lepers in the State of Sao Paulo alone is between two and three thousand. Valverde reports the exact number as 2307. The State of Parana is the last to be visited by the scourge; there are now 400 lepers within its limits. In the State of Santa Catharina the disease is not rare. In regard to leper asylums there is a difference of opinion as to whether a maritime or terrestrial location is superior. In the campaign against leprosy notification and isolation must be compulsory.—*Brazil-Medico.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

One Hundred and Thirteenth Annual Meeting, Held November 25, 1918.

THE PRESIDENT, DR. HOWARD CANNING TAYLOR, IN THE CHAIR.

IN addition to the usual routine business the annual election of officers was held and the annual reports of the Board of Censors, Counsel, and various committees were presented.

Report of the Counsel.—GEORGE W. WHITESIDE, Esq., presented this report, which showed that the Counsel's activities had been wide and varied, including investigations and prosecutions against druggists and laymen practising medicine, corporations, unlicensed physicians from foreign countries and the United States practising medicine without a license, investigation of the activities of electrotherapeutists, face specialists, chiropractors, naturopaths, and abortionists. The Counsel had made a very comprehensive translation and examination of 40 foreign language newspapers, as well as a number of English newspapers, of the advertisements of quack doctors and physicians who held themselves out as specialists in certain diseases. The Counsel had appeared on behalf of the Society before the Governor of the State of New York at the public hearing held in opposition to the Whitney Bill. The Counsel had been consulted frequently by various Departments of the City, State, and Federal Government, including the Department of Education, the Intelligence Department of the Army and Navy, the Character Committee of the Bar, the Health Department of the City and State of New York, the Police Department, the University of the State of New York, the Department of Justice and Port Alien Bureau, the Narcotic Squad of the Police Department, and many organizations and individuals. With all of these the Counsel had cooperated as far as possible and had been able to contribute from the files valuable information in response to inquiries from these sources. This line of activities was suggestive of the field of usefulness of the Counsel's office quite apart from the mere prosecution of individual cases in the endeavor to eliminate all obnoxious advertising. He had presented a memorandum on behalf of the Society for the Governor in opposition to the Whitney bill, calling attention to the fact that under this proposed act a physician's professional career might be suddenly cut short by the revocation of his license to practise if, by chance, or ignorance, he was convicted of a violation of one of the many technical provisions of this statute. The conviction of a lawyer for some technical misdemeanor did not of itself constitute grounds for the revocation of his license to practise law, and the facts must be such as to show some moral turpitude on his part before the Appellate Division would deprive him of this right to practise. There was no guarantee in this State that the misdemeanor for which the physician might be convicted might not be one of the most technical character and might not result in the revocation of his license to practise. Complaints against duly registered physicians that they were trafficking in narcotic drugs were largely responsible for the inadequate statutes which placed upon legitimate practitioners of medicine apparently unnecessary hardship in the use of narcotic drugs by them in their practice. The report included a brief outline of the prosecutions made by the Counsel during the year, and a list of alleged offenders against whom sufficient evidence could not be obtained to warrant prosecution.

Report of Committee on Public Health.—Dr. FRANCIS CARTER WOOD presented this report, which was read by the Secretary, showing that during the past year this committee had received no communications which could properly be assigned to the Committee on Public Health. He had, however, through his position as a member of the Advisory Boards of the Health Officer of the Port and the Commissioner of Health kept in touch with some of the public health problems which had confronted the medical profession during the past year. He had also had a number of conferences with members of the Public Health Committee of the Academy of Medicine on debatable public health questions and had attended a number of hearings on public health matters.

Report of Committee on Legislation.—Dr. GEORGE W. KOSMAK reported that the Committee had held regular meetings at monthly intervals during the session of the Legislature of 1918 to consider all the bills of interest to the medical profession. A total of 74 bills affecting directly or indirectly the interests of the medical profession of this State had been introduced at the last session of the Legislature, and were considered and discussed by the committee. The greater number of these bills were of little general importance. Attempts to invade and nullify certain provisions of the Medical Practice Act by the introduction of bills favorable to various schools of irregular practice were unsuccessful, as was also the renewed attempt to enforce an anti-vivisection measure. Among the more important legislative measures proposed were the following: (1) The Nicoll Bill, establishing a system of compulsory health insurance for individual workers and their dependents, which might be regarded as an attempt to improve the Mills Bill of the previous session. The medical features of this bill were framed without regard to the interests of the profession and would have resulted in ultimate establishment of a form of contract practice with its attendant evils. The Society, in a set of resolutions adopted at the regular meeting on February 25, 1918, had placed itself on record as opposed to this bill and had communicated with the senators and assemblymen as well as the presidents and secretaries of the larger county societies asking their assistance in defeating this measure. Although the interests of the medical profession were paramount, it must be regretfully admitted that the force of their presentation was not commensurate with this interest. The bill, however, was not reported out of committee, but there was every probability that a similar measure would be introduced at the coming session of the Legislature with better chances of its passage if supported by the same powerful interests that were instrumental in its introduction last year. (2) The so-called Whitney Drug Bill was introduced after various public hearings and was reported to the Governor who signed it without giving due consideration to the protests of physicians against certain of its features. This committee undertook to fight the passage of this bill, but failed because of the manner in which the bill was rushed through the Legislature. This bill created a department of drug control in charge of a commissioner and to this expensive and elaborate organization was given complete control of the sale and distribution of cocaine, opium, and their derivatives. While certain provisions of the act were less onerous than the Boylan Act, the measure as a whole must be regarded as a burden to the profession, since a part of the cost of the commission was derived from an annual tax levied on the members of the profession, which was practically a duplication of what the Federal Government had already enforced. Among other legislative enactments of the past year was the creation of a Bureau of Venereal Diseases in the State Department of Health for the diagnosis and treatment of venereal cases as well as public instruction in this field. Another bill provided for the compulsory reporting by clinical laboratories of all cases of communicable disease, specimens of which had been examined, to the local boards of health. Dr. Kosmak then recalled that in view of the generally unsatisfactory character of the relation between State Legislation and the medical profession, and after discussion with the Legislative Committee and members of the Society, he had presented resolutions at the 1918 meeting of the State Society which were adopted at that time. These resolutions provided that the Medical Society of the State of New York take steps to establish a Legislative Bureau at Albany which, under proper rules and regulations to be formulated by the Council of the State Society, should centralize and coordinate the work of the local committees on legislation, and that the necessary expenses connected with the conduct of this proposed Legislative Bureau be defrayed by the State Society, the funds to be secured by certain economies in the publication of the *State Medical Journal and Directory* and by extra assessment of the member-

ship of the Society if necessary. This resolution must be held in abeyance for the present owing to lack of funds. Finally, this committee recommended that instead of a committee of nine which was unwieldy and impracticable, that the Legislative Committee be composed of three or four members who could appoint local representatives in the various constituent Assembly districts, physicians who would be in a position to be actually acquainted with their local representatives in the Legislature and in this way could assure the latter of a closer interest in legislative enactments of a medical character. He hoped this matter would be taken up by the incoming administration.

Report of the Milk Commission.—Dr. ROWLAND G. FREEMAN presented this report, which showed that during the past year practically the same amount of certified milk had been supervised as during the preceding year, 14,244 quarts daily as compared with 14,598 last year. The committee was now supervising the production of certified milk on 19 farms. The inspector reported that farms producing bottled milk had a demand for all they could produce. All farms were hampered by a lack of labor and some were not keeping their barns filled, thinking that with the high cost of feed and the scarcity of labor a few cows well cared for were preferable to a larger number not kept in such good condition.

Committee on Compulsory Health Insurance.—Dr. WALTER LESTER CARR reported that this committee had held one meeting at which there had been a general discussion of the subject of Compulsory Health Insurance. It was agreed to cooperate in opposing the Nicolls Bill. There had been no other demand for activity on the part of his committee.

Public Health Education.—Dr. ESTHER L. JEFFERIS reported that this committee like the others had carried out its work under the difficulties of war conditions. The number of their workers was limited so the course of lectures had been shortened to six instead of eight as heretofore. After reviewing the subjects of the lectures and the names of the speakers, Dr. Jefferis stated that this committee had distributed 12,000 programs, that 300 posters had been put up in conspicuous places and hundreds of pamphlets had been distributed to teachers and children in the public schools. They had had, as in former years, the hearty cooperation of the newspapers, for which the committee wished on this occasion to express its gratitude and appreciation.

Report of Comitia Minora.—Dr. DANIEL S. DOUGHERTY presented this report, which showed that the Society had held eight stated meetings during the year, with a total attendance of 1460 and an average attendance of 183. The membership on Nov. 26, 1917, was 2779. Since that time 69 had been elected to membership in the Society, and 92 members had been lost, 47 by death. The membership at present was 2756, thus showing a net loss of 23 for the year. There had never been a year in the history of the Society during which it had lost so many members and so many prominent members as during the one just past.

On motion these reports were accepted.

Committee on Anti-Narcotic Drug Investigation.—Dr. JOHN P. DAVIN stated that his committee, in its report of March 25, after carefully considering the matter of drug addiction, had come to the conclusion that the addict was entitled to the same medical care vouchsafed to any other diseased or afflicted person.

It was therefore the duty of the medical profession to treat drug addicts as sick people and to safeguard their welfare and provide reasonable and intelligent medical procedure as in the case of other "diseased and afflicted" persons. After discussing the divergence of opinion as to the character of the condition known as drug addiction and the effects of the statute enacted at the last session of the legislature giving a commissioner of drugs powers hitherto unprecedented, the speaker said it was of great importance that the practitioner of medicine be placed in possession of reliable and authentic scientific, clinical and laboratory information as to the facts in respect to drug addiction, upon which there was at present so much controversy. He therefore moved that this Society request institutions equipped for laboratory and clinical research to make an investigation and estimation of such data as had already been offered or were available on this subject, and to place at the disposal of the practitioner of medicine at an early date the information concerning the same.

This motion was seconded and carried.

The Respiratory Tract as Portal of Entry for Infectious Diseases.—Dr. IRVING W. VOORHEES presented this paper, in which he said that it was going to be emphasized more and more that the majority of acute infectious diseases found a site of origin somewhere along the tortuous path of the airways. The recent study of carriers had served to emphasize the fact that an enormous number of people harbored infective bacteria which were harmful to themselves and were capable of starting a new infection on the membranes of susceptible subjects. The diphtheria bacillus, the *B. typhosus*, the pneumococcus, streptococcus, meningococcus and many others might exist in the nose and throat without giving any signs or symptoms of their presence. Physicians and nurses in the wards of hospitals frequently showed these germs in pure culture in the nose and throat and went about all unconscious of any danger. Such were temporary carriers; once they were away from the focus of infection for a few days the bacteria could no longer be found. An acute carrier was one who had had the disease and who throughout convalescence and for a few days thereafter carried the germs of his disease, while a chronic carrier continued to carry the germs for months or years thereafter. The study of carriers had shed new light on the spread of communicable disease, and had emphasized the necessity of taking at least two negative cultures from all cases before they were discharged from quarantine. The difficulty of sterilizing either the respiratory or intestinal tract after acute pathogenic infection was obvious, but it must be done if public health was to be safeguarded, and the newer teaching of medicine must demand and see that it was done. One of the greatest dangers was the missed case. This carrier question came into light very prominently during the early weeks that America was at war with Germany because of the development of cerebrospinal meningitis in cantonments. The experience of Great Britain with this problem had been a great help to us. In discussing the meningitis carrier, Dr. Voorhees reviewed the finding of the British Commission in which the conclusion was reached that every case of cerebrospinal fever was an instance of a carrier developing the disease. By culturing the nasopharynx these cases would be recognized within forty-eight hours. The British had tried a number of antiseptics to sterilize the nasopharynx and such other parts of the respiratory tract as seemed to be involved, and finally set down chloramine solution as the most effective. An apparatus designed for room disinfection, adapted to the spraying of steam, carrying also an aqueous solution of chloramine, was in use at the Rockefeller Institute, but it was cumbersome, raised the temperature of the room about 20 degrees, and could not be turned on and shut off promptly. Such a massive contrivance was not at all necessary, for the nasopharynx was very easily medicated by a simple method described later on in the paper. The exanthemata were all interesting examples of nose and throat infections which were localized for a very short time only and then became constitutional diseases with well marked and definite symptoms. Of the exanthemata, scarlet fever deserved most study because of its complications and the well marked characteristics upon which a diagnosis was based. It would seem that much could be done to shorten the course of scarlet fever by trying to cut off the foci of infection in the nose and throat. After discussing the part that the respiratory tract played in measles, diphtheria, whooping cough and parotitis, the author stated that tuberculosis of the upper respiratory tract was quite rare, and when it occurred was secondary to infection lower down. Primary tuberculosis probably never occurred in the nose, although it was possible that the nasal mucous membrane harbored tubercle bacilli for a short time, or until they worked their way down into the bronchi and lungs. The author mentioned that the bacillus of leprosy was frequently found in the nasal secretions, and considered somewhat at length common colds, influenza and pneumonia, calling attention to cold, exposure and fatigue

as factors in lowering resistance and increasing susceptibility to these infections. He said that acidosis also seemed to favor the action of bacteria, and therefore diet and medication directed to the increase of the alkalinity of the blood were indicated. After referring to the part played by the respiratory tract in focal infection he considered the treatment of infections of the respiratory tract, stating that the principles of treatment were in every case about as follows: (1) A culture should be taken, preferably on nutrient or blood agar. (2) The nose should be opened by means of astringents. (3) From a pint to a quart of irrigating fluid should be applied. (4) A sufficient quantity of a non-irritating antiseptic should be dropped or sprayed to kill the bacteria causing the infection. (5) This procedure should be repeated twice a day, or if need were urgent, every two hours. These principles varied only in detail according to whether one was working in the nose, larynx or bronchi. As to the culture, one must be sure that no antiseptic had been applied to the nose for at least three hours before taking. It was not safe to allow patients to irrigate at home. The successful use of any antiseptic was based on the rigid adherence to the following principles: (1) The antiseptic must be strongly bactericidal for all germs that were likely to infest the airways. (2) The antiseptic must not injure the mucous membranes through its activity or in the mechanics of its application. (3) There must be thorough contact with all infected parts and care must be taken to see that the antiseptic was not vitiated by dilution with the mucous membrane secretions. (4) Concentration of the antiseptic must be sufficient but not excessive in amount. (5) All conditions necessary to thorough bactericidal effect must be maintained over a sufficient period of time. Some antiseptics commonly used in the respiratory tract were argyrol, 5 to 10 per cent.; silvol, 5 per cent.; or silver nitrate, 2 per cent. solution in a de Vilbiss atomizer, No. 52, fitted with a hard rubber stem. He had also used menthol in oil from 5 to 25 per cent. with good results in cases that were not too severe in type. Nothing, however, had proved so efficient as dichloramine-T made up in a 2 per cent. solution in oil. The detail of making up this preparation was very important. As little heat should be used as possible in dissolving the powder in the oil, and every effort made not to contaminate either the bottle or the drugs. If possible, it was better to have the dichloramine-T fresh every day. He went into the detail of the preparation because he felt that poor results were due either to faulty technique or to the way in which the solution was handled afterward. In medicating the nasopharynx the patient lay down on a couch with the head extended far over and hanging freely, as in the position of operation for cleft palate. This made the nasopharynx dependent, so that any fluid dropped into it would remain as in a basin. A thin glass pipette 16 cm. long by ½ cm. in diameter, carrying a rubber suction cap like an ordinary medicine dropper, was passed directly backward, hugging the floor of the nose as closely as possible and about 1 c.c. of the dichloramine-T oil made as described was dropped into the nasopharynx, the patient remaining in this position as long as he comfortably could. In this way not only was the nasopharynx medicated, but the posterior ethmoid cells and the posterior pharyngeal wall. It was possible that some of the solution reached the sphenoid as well. In carriers, such as the meningococcus for example, this performance should be gone through with twice a day for two days, when cultures should be made once a day thereafter. After describing the details employed in the application of the dichloramine oil to the larynx and trachea, the writer expressed the opinion that the use of dichloramine-T was one of the most important additions to the knowledge of the treatment of infections of the respiratory mucous membrane which up to the present time had been brought to light.

Dr. JOHN E. MACKENTY discussed more particularly the subject of sinusitis, which he said was one of the most important factors in the etiology of systemic toxemia, and which he therefore preferred to call "chronic toxic sinusitis." This source of systemic toxemia was frequently not manifested in the course of an ordinary physical examination, yet it was frequently the cause of serious constitutional symptoms. This subject was first brought to the speaker's attention in 1907 when he himself was suffering from infection. Dr. MacKenty described the symptoms in his case, which he said was finally diagnosed as tuberculosis, because the doctors could find nothing else. As a result of a radiographic examination disease was found in his antrum, though there was no nasal discharge or any other evidence of sinus infection. This was because in this type of disease the general symptoms overshadowed the focal symptoms. The local manifestation was most important, and often the history of a case revealed a focal infection at some previous time. In searching for a focal infection one examination was not sufficient—it was often necessary to examine the patient twenty times in order to discover a chronic toxic sinusitis. Sometimes such a condition might be manifested only by a little pus coming from a sinus in the early morning. Headache, mostly in the region of the sphenoid or frontal sinus region, was suggestive of sinus infection. Frequently the radiograph was of little avail in revealing the condition. Migraine was often due to sinusitis. His object in speaking was to impress on the minds of his hearers the fact that one might have a sinusitis without local manifestations.

Dr. WALTER LESTER CARR said the subject was of particular interest in connection with the recent epidemic of influenza. It had become a routine to think that everything was all right if the tonsils and adenoids were removed, though perhaps we might have some doubt about the teeth. A point that was apparently forgotten was the lymphatic tissue of the pharynx. This tissue seemed to be very prominent as a seat of infection. Some children with infection had a discharge from the nose and accessory sinuses. During an epidemic of influenza it was well to remember that in dealing with it we were not dealing with the influenza bacillus alone, but frequently with secondary and more serious complications. The susceptibility to infection was not always the same, and different epidemics varied in intensity. The recent epidemic of influenza had nose bleed, pharyngitis, tonsillitis and laryngitis associated with bronchopneumonia, but with a slight evidence of lymph nodes involvement as detected by palpation. The lesson we had to learn was to guard against secondary infections in influenza and other infectious diseases that might cause serious complications and death. For this purpose a mild wash, such as Dobell's solution or physiological saline solution in a simple atomizer or dropper served the purpose. Free drainage of the mucous membrane was of course essential. Generally an appliance such as an atomizer or medicine dropper that the mother or nurse could use was sufficient. Unfortunately, in our enthusiasm for new antiseptics some of them had been used too strong, as dichloramine-T. Milder solutions, such as physiological saline or boracic acid seemed to be preferable for regular use. Argyrol, 10-15 per cent., used without washing off the mucous membrane before applying it, caused a thickening of secretion and was not effective. The benefit of sunlight, fresh air, and good hygiene in all infections should not be forgotten. The value of masks for physicians, nurses, and attendants to guard against secondary infections should be insisted upon, but the need for systematic cleansing of the nose and throat could not be overemphasized.

Dr. J. G. DWYER mentioned an investigation carried on during an epidemic of meningitis in an army camp in which it was found that sinus disease and adenoids were almost constantly present in meningitis carriers. As regarded influenza, it was pretty definitely proven that the Pfeiffer bacillus was the causative agent, but a strain having an increased toxicity. It would probably turn out like the pneumococcus, in that it would probably be shown that there were several types of influenza bacilli and that the one with which they had been dealing in the recent epidemic had an increased toxicity. Dr. Voorhees spoke of scarlet fever as a strentococcus infection of the nose and throat; he thought that the streptococcus in scarlet fever was in symbiosis just as it was in other sorts of infections, but that at the present time it was not considered the cause of scarlet fever. Another point was that we had been accustomed to think of the *Staphylococcus*

albus as a harmless organism, yet he knew of an instance of acute sore throat and sinus thrombosus in which the only organism that could be found was the *Staphylococcus albus*, and he knew of other instances in which it had shown itself more pathogenic than the staphylococcus aureus. The great difference between chronic sinus disease and other focal infections was that entire infection was closed in the labyrinth of the sinus and because of this we were coming to associate certain organisms with sinus disease. A point he wished to bring out was that advances in the bacteriology of the upper respiratory tract would be among the most important of future achievements in bacteriology.

Dr. Wolff Freudenthal observed that the reader of the paper spoke of tuberculosis as being a rare infection of the upper respiratory tract, but the speaker had swabbed out the pharynx in a great number of cases and found the actual tuberculous ulcer, bleeding, and the tubercle bacilli. If Dr. Voorhees would come to the Montefiore Home he would show him these primary tuberculous lesions in the nasopharynx, and he could demonstrate that they were primary tuberculous lesions both of the post nasal space and of the larynx. The more he observed the more thoroughly was he convinced that there are primary tuberculous lesions of the larynx. As to the cleansing of the nose and the methods advocated by Dr. Voorhees, they were very good, but in applying them one would have to differentiate between old persons and children. A child with high fever and a weak heart would have to be manipulated very carefully. Personally he believed that simple cleansing of the posterior nasopharynx with a simple iodine solution was best in young children, and in those a little older one might use a ½ per cent. cocaine and adrenalin and allow nature to do the rest.

Dr. Voorhees, in reply to the question as to whether it was a good thing to use argyrol on the ground that it was not wise to stop the secretions, said he quite agreed that it was not wise to stop the secretions until most bacteria were washed away or killed. He had used argyrol for the past ten years. It and the silver salts in general increased the secretions and killed bacteria. As to primary tuberculosis of the nasopharynx mentioned by Dr. Freudenthal, this did occur probably, but tuberculosis of the nose was usually associated with advanced tuberculosis elsewhere in the body. In regard to the use of antiseptic drugs on the mucous membrane of the nose and throat, we must bear in mind that we were dealing with a very delicate structure and for this reason dichloramine-T in chlorosane oil was preferable because it did not injure living animal tissue, but killed bacteria more quickly and effectively than any other similar agent. Dr. Voorhees thought it fair to say that a new era in the successful treatment of all respiratory diseases was about to be ushered in.

The Two Most Important Signs in Chronic Appendicitis.—Dr. Robert T. Morris read this paper. (See page 55.)

Dr. R. H. C. Gibbons emphasized the point that there were two kinds of tenderness associated with the appendix, the exquisite tenderness distinguished by McBurney and a lesser tenderness to which attention had been called by George Edebohls. He thought with these in mind one should be able to diagnose appendicitis. As Mr. John B. Murphy had said, "when one found pain in the region of the appendix, fever and vorsiting, one should look for trouble." If a patient presented these symptoms one was safe in telling him that he had appendicitis of low grade. McBurney was the man to whom credit should be given for the solution of that most treacherous of all diseases, the diseased appendix.

Cerebrospinal Meningitis and the War.—The year 1915 seems to have been a record one for this affection in France and England. In the zone of war activities in France the number of cases was 1073 and in England the incidence was 2566. In 1916 there was a notable falling off in both countries, which was maintained in France, although in England a high morbidity occurred in 1917. Less than half the English cases occurred in soldiers.—*Pathologia.*

EXPERIMENTAL EVIDENCE AS TO IMMUNITY FROM TUBERCULOUS INFECTION.

By GEORGE E. BUSHNELL,

Colonel, M. C., U. S. Army, Retired.

WASHINGTON, D. C.

Our interest as clinicians in the study of the natural history of tuberculosis does not center upon the tubercle bacilli but upon the tissues of the human body that resist them. We wish to know the laws of resistance, the conditions which favor and those which oppose the growth of the tubercle bacilli. To accomplish this we must institute our experiments in such a way as to imitate as closely as possible the conditions of natural infection; and even natural infections if primary and massive, as, for example, the infections which lead to the acute generalized miliar tuberculosis of the infant, because hopeless are of relatively small interest to us except from the standpoint of prophylaxis. We especially desire to know what can be learned from the smaller artificial inoculations with tubercle bacilli.

The greatest mistake that has been committed in animal experimentation has been to give too large infecting doses, especially as they are usually given by methods that break through the natural defensive mechanisms of the body, that is to infect in ways which can never or but rarely occur in nature. When we study the results of experiments in subcutaneous inoculation we should reflect that in the first instance the injecting needle has broken through the barrier of the skin and pierced small venules, depositing, moreover, its contents in a part, the subcutaneous tissue, which is not designed by nature for the task of defense of the organism. Furthermore, the creation of a depot or deposit of tubercle bacilli with the inevitable result of a caseation has led to the formation of what is practically an artificial tubercle. Hence the animal has what might be called the unnatural task of coping with a prematurely formed tubercle before it has had the opportunity to develop its defensive mechanisms—something that never occurs in nature—with the additional disadvantage of permitting the penetration of the invading organisms into the blood instead of confining them, as in natural conditions, to the lymphatic system at the outset. In primary infections by the intravenous method, which is essentially an artificial bacteremia, we have a method of infection which can likewise never occur under natural conditions, in which tuberculous bacteremias are always secondary to local infections. If we institute feeding or inhalation experiments we should bear in mind that animals rarely have the opportunity to ingest millions of tubercle bacilli and that if they inhale the bacilli it is not in the form of a finely divided spray propelled by a powerful pump and continued until the lungs are completely filled with the watery particles. It is a common error to apply the results of experimentation upon unprotected animals, primary inoculation, to the chronic pulmonary tuberculosis of the human adult, a process which always develops in the already infected, and, therefore, to some extent protected, organism, a secondary form of tuberculosis. Another error is to draw conclusions from the phenomena of the period which immediately follows the primary inoculation of animals, the period of sensitization, as to what is to be expected in human pulmonary tuberculosis in which there has been ample time to create a well developed and mature immunity. If we reject experiments in which these errors have been committed we shall at once dispose of a large proportion of the experimental data on record. In so far as concerns experiments that have been wisely planned and are worthy of consideration we should still in our study of them bear in mind constantly that allowances are to be made for the unnatural conditions of the experiments which arise from the necessity under which the investigator has labored of employing a dosage excessive in comparison with the probable dosage of natural infection with a view to producing infection within a reasonable time and in such a way as to exclude the probability of confusion with intercurrent natural infections. The conditions of artificial inoculation may, then, in many respects be less favorable for the development of immunity than those of the natural infection. On the other hand, however, the artificial bacteremia is more favorable than the natural bacteremia because it may be created when the animal's resistance is at its best whereas large natural bacteremias can only occur when resistance is lowered to the point of permitting softening and ulceration of glands, rapid proliferations of bacilli, etc. Hence anaphylactic death which may occur in immunized animals after large reinfections is never met with in the natural bacteremias because irruption of bacteria into the blood current or their multiplication within blood vessels does not occur when resistance is high enough to produce a rapid bacteriolysis. We must then be cautious in applying to man the results of animal experiment. Indications of the highest value are afforded by it, but, after all, the conditions are not entirely comparable with those of the naural course of tuberculosis.

In what follows it is proposed to describe briefly some of the experiments which throw the most

light upon the facts of the development of acquired resistance to tuberculosis under natural conditions.

Koch's "fundamental experiment" led to the treatment with tuberculin, and upon it as the first stone has been erected the whole structure of the theory of immunity in tuberculosis. "The inoculation wound of a healthy guinea pig which has been injected subcutaneously seems at first to heal. But in the course of ten to fourteen days a hard nodule forms which soon breaks down and remains as an ulcer until the death of the animal. But animals already tuberculous behave differently. Most suitable are guinea pigs which were inoculated four to six weeks previously. In such an animal no nodule forms at the point of injection, but the latter becomes hard and has a peculiar color. It soon appears that the skin is necrotic. It is cast off and a shallow ulceration remains which generally heals rapidly and permanently without the neighboring lymph glands becoming infected."[1] From this observation it appears that the tissues of the already infected animal including the lymph glands react differently to a reinfection. Experiments that throw light upon the nature of these changes will be considered in the following pages:

THE PRIMARY SUBCUTANEOUS INOCULATION.

The period of incubation is the time which elapses between the day of infection and the appearance of manifest pathological changes. The length of this period varies in general inversely with the size of the infecting dose. At about the same time as the swelling and reddening of the point of inoculation the regional glands begin to swell. With very small doses the swelling of the glands may appear much earlier, with large doses considerably later than the changes at the point of inoculation.

Grüner and Hamburger[2] give the average periods of incubation as follows:

After Infection With	Changes at Point of Inoculation Appear	The Gland-Swelling Appears
0.5 mg. T.B.	After 6 days	After 8 days
0.005 mg. T.B.	After 9 days	After 10 days
0.0005 mg. T.B.	After 12 days	After 9 days
0 00001 mg. T.B.	After 25 days	After 20 days

They tested the behavior of the tissues, as altered by the first injection, on reinfection with tubercle bacilli. Guinea pigs infected primarily with 0.0005 mg. human tubercle bacilli were reinfected with 0.5 mg. of the same. If reinfection occurred on the fourth day after primary infection, six days were required before the point of reinfection showed signs of inflammation. But if reinfection was done on the sixth day after primary infection, the point of reinfection showed distinct reddening and infiltration in twenty-four hours. The sensitiveness increases, for the reddening and infiltration were more marked in animals reinfected on the eighth than in those reinfected on the sixth day and still more marked in those reinfected on the tenth day. These changes at the point of reinoculation may anticipate the visible alterations at the point of the original injection. Moreover, the phenomena obtained at the point of reinoculation are not dependent upon proximity of the point of reinoculation to the point of primary infection. They are seen if the reinoculation is done in any part of the body. Hence we conclude that before even swelling and redness mark the local reaction at the place of the original introduction of the tubercle bacilli, the whole body has begun to undergo a change toward the tubercle bacilli characterized by an increased rapidity of inflammatory reaction to their presence which appears to be even more marked elsewhere than it is in the lesion inflicted by the primary injection.

The tuberculin reaction is closely analogous to the reaction to tubercle bacilli and is, of course, used much more as a proof of the existence of a tuberculous infection and as a measurement of the sensitiveness of the organism to it. It is probable that all subjects who have come in contact with the tubercle bacilli can be made to react positively to tuberculin by sufficiently large doses frequently enough repeated, but in practice a considerable percentage of mature adults do not react to tuberculin as usually administered. In young children a positive tuberculin reaction is usually evidence that the disease is present in an active, though not necessarily clinically important, form. And in general a ready response to tuberculin is to be regarded as a proof that the organism has recently been obliged to summon its forces for defense. There is, then, an ill-defined period in the life of the tuberculous individual and also in that of those vaccinated against tuberculosis by a small infection in which there is a sensitization to tuberculin.

The irregular manifestation of tuberculosis, gland tuberculosis, bone and joint tuberculosis, tuberculosis of the skin, etc., as they occur in children are ascribed by some to a sensitization to tubercle bacilli which leads to the holding fast of the bacilli wherever they may be found in the body with the result that tubercle foci are developed. These forms of tuberculosis, really ascribable to a slow and imperfect development of immunity rather than to an active process of arrest of the bacilli, is called the period of sensitization to tuberculosis, or by Ranke the period of the immediate reaction. Now sensitiveness to tuberculin is not incompatible with a high degree of immunity to tuberculosis and the forms of tuberculosis mentioned above, while they are evidence that much is lacking to the attainment of a perfect immunity, are still found in periods of the disease in which there is sufficient immunity to localize the tuberculous foci and in which, to judge from animal experiments, new infections from without would not take root.

Quite different from these kinds of so-called sensitization is the period of sensitization immediately following the primary infection, whether artificial or natural, a knowledge of which is necessary in order to understand the mode of development of immunity and to judge the results of animal experimentation. Those who first repeated Koch's fundamental experiment obtained results which seemed to contradict his findings, showing rather an impairment than an increase in resistance as the result of the first infection. Bail's experiment, for example, is almost as famous as Koch's. Bail[3] found that if an already tuberculous guinea pig is reinfected with 100 mg. of tubercle bacilli intraperitoneally, it dies within a few hours, while a normal guinea pig infected for the first time with the same dose of tubercle bacilli lives two or three weeks. Without attempting to give an account of the historical

development of the knowledge of this obscure subject, it is sufficient for us to say that further study has now made it clear that reinfections while the processes of immunization are in their infancy are prejudicial to the development of immunity and in fact hasten the development and the generalization of tuberculosis. Gilliland[4] says: The animal vaccinated against tuberculosis with human tubercle bacilli during the period of vaccination and for some weeks afterward is more liable to contract tuberculosis than a normal animal. The natural resistance of the animal is lowered during the time of vaccination. Calmette[5] says that animals isolated after a single infection of average intensity made artificially by the digestive tract almost always get well and for at least a year, perhaps longer, they are no longer susceptible to reinfection even by the ingestion of enormous quantities of virus through the oesophageal tube. On the other hand, cattle which have absorbed several times at intervals of days or weeks minimal doses of virulent bovine tubercle bacilli never get well. They acquire a severe tuberculosis with course the more rapid the more frequent the infections have been. The most common mistake in experimentation with a view to determine the presence of immunity is to reinfect at too early a date. Römer[6] on the basis of his experiments with the vaccination of cattle with bovovaccine against tuberculosis makes the rule that no reinfections should be performed in order to test the immunization until at least three months, preferably six months, have elapsed after the original inoculation. Dietl and Hamburger[7] have published work on what they call tuberculous exacerbation in which they show that while an immunity is undoubtedly acquired from the original infection that immunity does not prevent the breaking down of the skin at the point of reinfection, the swelling of lymph glands in connection with the second infection, etc. But upon study of the protocols of their experiments it appears that the primary infection was made on June 11 and the reinfection on July 17, but little more than a month later. Instead, therefore, of testing the immunity, Hamburger was really interfering with the successful production of an immunity.

THE BEHAVIOR OF THE REGIONAL LYMPHATIC GLANDS.

As has already been stated, the nearest gland of the region in which the point of inoculation is situated swells at about the same time as the first changes appear in the skin over the depot of bacilli.

The swelling of the glands is due, of course, to their invasion by tubercle bacilli from the point of inoculation. This takes place very quickly and not only the nearest gland but a series of glands and gland groups are involved, usually in a centripetal direction. Hamburger cites the experiment of Nötzel who, injecting the knee joint, found tubercle bacilli in the inguinal glands in five minutes and later in the iliac and lumbar glands. The swelling of the more distant glands is progressively less marked in each gland as the infection proceeds upward. And not only the lymph glands, the viscera are also infected at a very early time. Grüner and Hamburger were able to show that the spleen of the guinea pig contains tubercle bacilli on the ninth day after infection. The organ showed no histologically recognizable tuberculosis, but the presence of the bacilli was demonstrated by the inoculations upon normal guinea pigs. This is usually considered to denote the penetration of tubercle bacilli into the blood stream and their transportation by this route to the vicera. It is not impossible, however, that the transport was by the lymph channels. But the importance of the observation, is this, that it shows that after subcutaneous injection tubercle bacilli are very widely spread through the body in a brief space of time. While in a feebly resistant animal like the guinea pig, which has received what will prove a fatal dose, such dissemination may, and usually does, lead to the formation of so many manifest foci, in animals of higher resistance or even in the guinea pig with very small doses the smaller collections of tubercle bacilli do not go on to produce manifest tubercles. This is, of course, much more marked in the partially immune animal than in the "fresh" animal. Examples of latency of the depots of tubercle bacilli will be given further on in this paper.

PRIMARY INOCULATIONS. LARGE DOSE.

Römer.[6] Guinea pig injected Oct. 3, 1908, with 1/1000 mg. virulent bovine tubercle bacilli subcutaneously. Died, Dec. 23, 1908. Autopsy, large, cheesy infection tumor, neighboring glands caseous. Enormously extensive miliary tuberculosis of liver, spleen, and lungs.

Hamburger.[9] Guinea pig. Intraperitoneal injection 1 c.c. thick suspension human tubercle bacilli, Feb. 6. Died, April 28, with miliary tuberculosis. Tubercles in peritoneum, spleen, liver, lungs, hemorrhagic peritonitis. These are examples of the usual course of infection of the guinea pig with even small doses (as in first example) of virulent tubercle bacilli. Little is to be learned of the development of an immunity from such experiments. But even so feeble a resistance as that of the guinea pig is not altogether helpless in the presence of tuberculous infection if only the dose is sufficiently reduced, as is shown in the following examples:

Römer and Joseph.[2] Guinea pig infected with 1 mg. bovovaccin (attenuated human tubercle bacilli) subcutaneously. Killed in eleven months. Cheesy nodule at infection site. Enlarged axillary gland; otherwise no tuberculosis. Guinea pig infected with 1 mg. bovovaccine subcutaneously; infection node formed and subcutaneous glands enlarged which later diminished in size. Lived fourteen months; cause of death unknown. Knee-fold gland cheesy; other organs without change. The cheesy gland, inoculated into another guinea pig subcutaneously caused death in three months from typical inoculation tuberculosis of enormous extent. Guinea pig infected with 1 mg. bovovaccine subcutaneously; typical tuberculin sensitiveness, infection node present; subcutaneous glands enlarged. Killed moribund in twenty-two months; cheesy infection node, left axillary gland enlarged, firm; spleen slightly enlarged; lungs rather abundant gray foci; lung contracted in their vicinity.

We note in the foregoing examples that two of the guinea pigs lived respectively eleven and fourteen months, and so far as tuberculosis is concerned, might have lived a much longer time, the infection having been so weak that the animals had time to localize the disease and develop a successful resistance. How high the immunity was is shown by the

fact that the cheesy gland in the second example contained enough tubercle bacilli to cause death from acute infection in another animal. Note here that the immunity did not consist in destroying the bacilli, which, on the contrary, were living and virulent. This and other instances which will be cited further on show how small a part bacteriolysis plays in successfully resisting tuberculosis. In the third example the same dosage produced a more generalized infection. Still the animal lived a very considerable time considering the normal duration of the life of a guinea pig and the contraction of the lung about the tuberculous foci shows an effort at resistance by the development of fibrous encapsulations. Death in this case does not appear to have been produced unmistakably by tuberculosis, though the tuberculous process was undoubtedly progressive. In every series of experiments of this kind one must be prepared for individual differences of the animals in natural resistance and in the ability to acquire increased powers of resistance. These differences do not depend upon the age or weight of the animals, but upon some vital property, the nature of which is not understood. In predicting, therefore, the development of immunizing reactions we must expect that some of the individual animals will be less successful than others in their resistance to the tuberculosis.

	First Infection.	Second Infection.	Death.	Autopsy.
Principal	Jan. 6, 1908, 1/5 mg. 10 day bovovaccine subcutaneously, left shoulder.	June 4, 1908, 1/10,000 mg. swine tubercle bacilli, right shoulder.	Dec. 19, 1908.	Left shoulder, two cheesy nodules. Left axillary and knee glands caseated. Right shoulder, fibrous node. No gland changes. Spleen somewhat enlarged, two small tuberculous foci. Liver normal. Lungs, diffuse hepatization. Upper lobes adherent. Culture shows human tubercle bacilli.
Principal.	Jan. 6, 1908, 1/5 mg. 10 day bovovaccine subcutaneously, left shoulder.	June 4, 1908, 1/10,000 mg. swine tubercle bacilli, right shoulder.	Still livea (May 1, 1909)	Left shoulder, node from first infection. No recognizable result from second infection.
Control for first infection.	Jan. 6, 1908, 1/5 mg. 10 day bovovaccine subcutaneously, left shoulder.	.....	Sept. 1, 1908.	Left shoulder caseous node. Small caseous axillary and knee glands. Spleen slightly enlarged, granulated. Liver some necrotic apots. Lungs partly adhereot to chest wall, upper lobes diffuse cheesy pneumonia, lower lobes numerous small tuberculous foci.
Control for second infection.	.....	June 4, 1908, 1/10,000 mg. swine tubercle bacilli, right shoulder.	Oct. 4, 1908.	Right shoulder, cheesy node size walnut. Axillary and knee glands caseous. Spleen enormous. Liver and lungs full of gray miliary tuberculous foci.

EXPERIMENTS IN TUBERCULOUS REINFECTION.

Method—Animals are infected with a small dose of turbercle bacilli and after a suitable interval the immunity acquired as the result of the infection is tested by reinfection with a much larger dose of bacilli. Other normal animals are given the first infection only in some cases, the second infection only in other cases, so that they may serve as controls respectively for the two infections. An example from Römer using guinea pigs:

Immunity is only derived from contact with living and virulent tubercle bacilli. To prove the fact that previous treatment with dead tubercle bacilli or with tubercle bacilli avirulent for the animal produces no immunity, Römer made the following experiments:

Guinea pigs previously treated with dead tubercle bacilli, April to July, 1907:

	First Infection.	Second Infection.	Killed.	Result.
Principal.	Various preparations of dead tubercle bacilli.	June 4, 1908, 1/10,000 mg. swine tubercle bacilli, right shoulder.	Sept. 7, 1908.	Walnut sized cheesy tumor. Caseated axillary and knee fold glands. Numerous tubercles, lungs, liver, spleen.
Control.	Various preparations of dead tubercle bacilli.	.....	Sept 7, 1908.	Free of tuberculosis.

Guinea pigs previously treated with avirulent tubercle bacilli:

	First Infection.	Second Infection.	Death.	Result.
Principal.	June 6, 1907, 1/2 mg. Avian tubercle bacilli, left shoulder.	June 4, 1908, 1/10,000 mg. swine tubercle bacilli, right shoulder.	Sept. 22, 1908.	Caseous ulcer, right shoulder, caseous axillary and kneefold glands. Spleen enlarged. Lungs completey filled with cheesy foci.
Control.	June 6, 1907, 1/2 mg. Avian tubercle bacilli, left shoulder.	.....	Killed Sept. 22, 1908.	Free of tuberculosis.

Treatment with dead or with living but avirulent tubercle bacilli produced no visible signs of immunity.

In the experiment with living and virulent tubercle bacilli the bovovaccine, though given in smaller dose, appears to have been stronger than in the examples cited previously. Comparing the autopsy of the principal that died with that of the control for the first infection we find a great similarity. In both there were local evidences of the injection in caseous nodes and enlarged and caseous neighboring glands. In both the spleen is somewhat enlarged. The lungs are the seat of a fatal pneumonia, apparently more advanced in the control, the condition of the liver is better in the principal. Culture from the lungs of the principal shows tubercle bacilli of the human type. The node

of the right shoulder is, of course, due to the second infection. It is quite evident from this comparison that the condition of the principal was at least no worse than that of the control. It is to be noted that this animal lived about three and one-half months longer than the control for the first infection. This is quite common in infections of this kind, as if the second infection, instead of harming, actually benefited the tuberculous animal, perhaps by stimulating his immune processes. The second principal, still alive one year and four months after the first infection, is a much more successful case than the first. Examining now the control for the second infection, we find an enormous spleen with lungs and liver full of tubercles, death having occurred in four months after infection from acute tuberculosis from the very virulent strain of swine bacilli which was used for the second infection. There can be no question that the effect of the first slight infection was to confer a high degree of immunity, even though in one case it led to death from tuberculosis, in that it enabled the doubly infected animals to resist with ease reinfection with virulent bacilli.

It will be noted that in those of the foregoing experiments in which the primary infection was made with virulent bacilli, the point of reinfection was represented by a fibrous node or by no changes which could be detected by palpation, and the neighboring glands are stated not to have been enlarged, while as a rule at the site of the primary infection there is an ulcer or a caseous node. This agrees with the findings in Koch's fundamental experiment. The primary inoculation is attended by swelling of the adjacent lymph gland or glands. A depot infection if the infecting dose has been of some size results in a tubercle which caseates and may or may not break down into an ulcer. In infections of the pharynx, throat, and intestines, the point of entrance is usually free of macroscopic changes. From the facts of depot infection the general law has been deduced that the primary focus leads to enlarged and caseated glands and that conversely enlarged and caseated glands point to the fact that the primary focus is or has been situated in the area drained by these glands.

From this law erroneous deductions have frequently been made as to the site of the portal of entry of tubercle bacilli into the body. There is just this much truth in the law as a general law, that when the primary infection is large, as in depot infections and sometimes in infections through the pharynx or intestines, the nearest regional gland swells greatly, the lymph channels are blocked, and the inflammation tends to remain for a time localized. But in case of small infecting doses which are probably the rule in natural infection, the infection does not produce marked swelling in the nearest gland, this gland does not become blocked, and the infection travels on in diminishing amount through the series of glands to which the gland first infected belongs. In cases of this kind it may be impossible, at least during life, to determine the portal of entry. Another law of wider application is that primary infections are characterized by swelling of the gland, in secondary infections the glands do not swell. The fact that in reinfection the glands do not become enlarged at all or enlarge but slightly and for a relatively short time has attracted much attention. Weleminsky[10] goes so far as to speak of an especial immunity of the lymphatic system as an effect of the primary infection. It is believed, however, that the failure of the glands to become inflamed when secondary infections are made in their vicinity is simply a manifestation, though an especially striking one, of the fact which we have seen illustrated in the foregoing experiments that all parts of the body of a tuberculous animal become insensitive to reinfection. This law applies especially to artificial depot inoculations.

In tuberculosis of the lymphatic system there may be a chain of glands of which some of the larger glands are swollen and caseated, while the intervening glands remain small and appear normal to macroscopic inspection. That it would be erroneous always to draw conclusions as to the portal of entry from the location of the largest glands is best shown by the fact that sometimes the tracheobronchial glands alone swell in infections made at a distance from the lungs.

The objection having been made that, since spontaneous tuberculosis apparently progresses unhindered, the facts as to protection against tuberculosis from infection with cultures of tubercle bacilli would not apply to infections with "animal" tubercle bacilli (*i. e.* tubercle bacilli derived directly from the body of a tuberculous animal), Römer and Joseph[2] instituted a series of experiments to answer the questions: First, what is the result of infecting animals with tubercle bacilli adapted to live in the animal body? and, second, is the tuberculous animal especially sensitive to tubercle bacilli which have adjusted themselves to the conditions of its own body?

Method—An axillary gland is extirpated from a tuberculous animal the first infection of which has been made by subcutaneous inoculation with human tubercle bacilli into the shoulder. The gland is at once rubbed up into an emulsion in physiological salt solution and 2 c.c. of this emulsion injected into the owner of the gland and also into a normal guinea pig as the control for the second infection.

The following is an example of these experiments:[2]

	First Infection.	Second Infection.	Death.	Autopsy.
Principal.	July 29, 1909, 1 10,000,000 mg. T.B. left shoulder.	Jan. 28, 1910, 2 c.c. gland emulsion right shoulder.	Killed June 13, 1910.	Left axillary glands (two) size hazel nut. Right shoulder perfectly smooth. Bronchial glands pea-sized. Left apex, focus, size grain of rice. Spleen slightly enlarged.
Control for first infection.	July 29, 1909, 1 10,000,000 mg. T.B. left shoulder.	....	Killed June 13, 1910.	Left axillary gland size walnut, kneefold gland size pea. Lungs 5 foci size pinhead. Left apex adherent. Small cavity left apex. Bronchial glands size lentil. Spleen slightly enlarged.
Control for second infection.	....	Jan. 28, 1910, 2 c.c. gland emulsion (from principal) right shoulder.	Killed June 13, 1910.	Right shoulder several caseated infection nodes. Caseated axillary and kneefold glands, pea to bean-sized. Severe tuberculosis lungs and liver. Tuberculosis of spleen.

There can be no question that the very slight disease of the principal dated solely from the first infection, and that the second infection, which produced severe tuberculosis in an unprotected animal, had no effect whatever upon it, though this infection was performed with the use of tubercle bacilli from its own body. This experiment well shows that the immunity toward reinfection is not simply a local immunity (*i. e.* confined to the neighborhood of the point of inoculation, in this instance in the subcutaneous tissues), but that the rest of the body is also immune.

In another series of experiments[8] one guinea pig, originally infected with bovovaccine, and another which had spontaneous tuberculosis of the cervical glands, were subjected to reinfection with 1/1000 mg. swine tubercle bacilli injected subcutaneously in the right shoulder. The point of the second infection in both animals showed no visible alterations. Four months after the second infection a small bit of tissue excised from this place in both animals was inoculated by Römer into two normal guinea pigs subcutaneously, both of which died of miliary tuberculosis in about six months. In these experiments the animals had shown themselves entirely immune, so far as any evidence of an active process was concerned, to the virulent tubercle bacilli of the second infection, the immunity being as marked in the case of spontaneous tuberculosis as in the animal artificially inoculated, but the tubercle bacilli of the second infection were, nevertheless, proved to be living and virulent. Notwithstanding this extraordinary resistance, both of the doubly reinfected animals died some four months later, proof that the primary tuberculosis was the cause of death in the animal inoculated with bovovaccine being afforded by the fact that cultures from its lungs showed tubercle bacilli of the human type.

We have seen (table, p. 93) that the cheesy gland which resulted from the primary infection of a guinea pig which otherwise resisted the disease successfully for fourteen months likewise contained sufficient living tubercle bacilli to produce early death from enormously extensive tuberculosis in an unprotected animal. In both of these cases the immunity developed as a result of the primary inoculation sufficed to restrain large collections of tubercle bacilli from extending. The difference between the two cases is, of course, this, that in the animal with the cheesy gland, this infection had taken place before immunity had been acquired; the infection being slight in severity, opportunity was afforded to develop sufficient immunity to localize the disease, but that immunity was powerless to do more than to encapsulate the cheesy focus, whereas in the other animal a certain immunity having been already acquired, the more virulent bacilli of the reinfecting injection were prevented from forming a caseous focus or from giving any sign of even the slightest inflammatory reaction, and that, too, although the original tuberculosis in both cases was destined to lead to the death of the animal within a few months. Here is a paradox which may well furnish food for reflection: An animal fatally ill with tuberculosis possesses a complete immunity to lethal doses of tubercle bacilli of a strain much more virulent than that of its original infection. The only explanation for this can be that the general immunity acquired in even an unsuccessful attempt at resistance to tuberculous infection is strong enough to resist absolutely second infections with tubercle bacilli, though it may not be strong enough to prevent the spread of tubercle bacilli plus a collection of their poisonous products. This experiment illustrates from another point of view the fact derived from daily observation that the consumptive is able to localize his disease for many years, though it may ultimately cause his death. If we put the facts in this way he is not subject to extensions, so long as his immunity is maintained, from bacilli that escape into the blood from his lesions—we shall make clearer the analogy that exists here, and we may add that if the tuberculous individual is able to resist thus his own bacilli he is much more able to resist those that may come to him from without, irrespective of the relative virulence of the tubercle bacilli thus acquired.

Römer[11] reports very numerous experiments in tuberculous reinfection of the guinea pig, not only by subcutaneous injection, but also by inhalation and ingestion of tubercle bacilli and by contact with animals with open tuberculous ulcers, all of which point with more or less distinctness to an immunity against all subsequent infections derived from a previous infection. While the guinea pig is the cheapest and most easily handled of all the animals of experiment, so that the use of guinea pigs is practically unavoidable in extensive experimentation, the resort to this animal has the objection that when once tuberculous, however slight the infection, he goes on, as a rule, to develop a progressive and fatal tuberculosis. To decide whether there is evidence of the existence of an immunity it is necessary in such cases to compare with care the lesions of the principals with those of the controls, to determine in some cases the strain of tubercle bacilli which can be cultivated from the lesions, to consider the comparative length of life of the various animals, etc. In short, the results, while very significant, require careful analysis. They are not so conspicuously successful as to command immediate acceptance.

In a later series of experiments, Römer,[9 11] therefore resorted to the sheep, an animal which, he says, has about the same resistance to tuberculosis as man. The success of these experiments is much more marked.

Bits of lungs of Sheep Nos. 47 and 51 were inoculated into guinea pigs which when killed in three months were found free of tuberculosis.

LATER HISTORY OF SOME OF THE SHEEP.[11]

Sheep No. 83, killed June 25, 1911. Was in good health and at its best weight. At point of first injection there was a wulnut-sized focus containing crumbly cheese, partly calcified. The shoulder gland was enlarged and firm and contained crumbly cheese, surrounded by a firm connective tissue capsule. Otherwise, no tuberculosis. Two years after the last infection, this sheep was, therefore, shown to have been fully immune not only to the second subcutaneous injection, but also to the third severe intravenous injection which killed the control in eight months.

Sheep No. 58 was given another reinfection intravenously with 2/10 mg. TB per 10 kilos, on July 7,

1911; suffered from high fever and intense dyspnea and died July 9, 1911, of anaphylaxis. Autopsy: No evidence of the first infection subcutaneously. In the lungs, small isolated gray-yellow tubercles. Marked edema.

	First Infection.	Second Infection.	Result.	Remarks.
Principals Nos. 83, 58, 59.	Aug. 6, 1908, 1/10 mg. per 10 kilos subcutaneously.	June 25, 1909, 2/10 mg. per 10 kilos intravenously.	Still alive, clinically healthy	Sheep 83 had in addition 2/10 mg. per 10 kilos Oct. 27, 1908. (Weight of sheep between 20 and 30 kilos.)
Nos. 47, 51.	Oct. 27, 1908, 2/10 mg. per 10 kilos subcut.	June 25, 1909, 2/10 mg. per 10 kilos intravenously.	Killed April 29, 1910 (47). May 5, 1910 (51).	Subcutaneous infection node size walnut (inj. Oct. 27, 1908). Otherwise free of tuberculosis.
Controls first infection No. 80.	Aug. 6, 1908, 1/10 mg. per 10 kilos subcut.	.....	Killed Feb. 18, 1908.	Infection node size walnut, otherwise free of tuberculosis.
No. 49	Oct. 27, 1908, 2/10 mg. per 10 kilos subcut.	.....	Killed April 29, 1910.	Infection node aize walnut, otherwise free of tuberculosis.
Control second infection No. 99.	.....	June 25, 1909, 2/10 mg. per 10 kilos intravenously.	Aug. 25, 1909, died of tuberculosis.	Lungs completely filled with equal-sized and equally distributed miliary tubercles, bronchial glands much swollen, contain tubercles. Abdominal organs without (macroscopic) changes.

Sheep No. 59 had the same infections as Sheep No. 58. Last injection was followed by high fever and dyspnea as in Sheep No. 58, but these symptoms abated quickly. It died, however, on Aug. 12, 1911. Autopsy showed distomiasis of the liver. There was a node on the left shoulder containing crumbly cheese. Sparse pea-sized tuberculous foci in the lungs.

Sheep No. 33. After violent fever reaction from infection of Nov. 22, 1909, it lived in the best of health until the end of June, 1911. Then it became sickly and died on Aug. 11, 1911, of severe distomiasis of the liver. A bean-sized node of firm connective tissue was present at the point of injection containing quite dry cheese. The neighboring shoulder gland was in a similar condition. In the lungs there were sparse and in part completely calcified foci. No caseation anywhere. Abdominal organs normal. This animal had three injections: On Sept. 20, 1906, 1/100 mg. per 10 kilos subcutaneously; on Aug. 6, 1908, 1/10 mg. per 10 kilos subcutaneously; on Nov. 22, 1909, 1 mg. per 10 kilos intravenously. Control died in four weeks. The dose of Nov. 22, 1909, was 5 mg., equaling 200 millions TB. The second infection, Aug. 6, 1908, was equal to 16 millions TB. There was no sign of these infections, the only evidence of tuberculosis dating from the first infection of only 1.6 millions TB.

were completely filled with gray miliary tubercles, confluent in places. Bronchial and mediastinal glands were much swollen, but presented no distinct foci.

The foregoing tables are reproduced (with some modifications as to form) from Römer's work on account of their importance as evidence of the height which immunity from tuberculous infection may reach in the naturally resistant animal. They should be carefully studied by all who desire to understand the immunity of man to tuberculosis. Attention is called to the fact that Sheep Nos. 47 and 51 acquired a durable immunity from the same dose subcutaneously, that given intravenously killed Sheep No. 99 in two months with miliary tuberculosis, showing the great value to the infected animal of any measures calculated to localize the infection. It will be noted that some of the sheep, notably Sheep No. 92, did not acquire a sufficient immunity to restrain entirely the development of a tuberculosis of lungs and glands. Römer leaves it an open question whether the lung tuberculosis of Sheep No. 92 dates from the first or second infection. However that may be, there is no doubt that the first infections (estimated at 1.6 millions of tubercle bacilli) were large infections, quite beyond what might be expected under natural conditions. That any of the sheep were able to overcome completely so large a primary infection is truly remarkable. We have already noted the fact that under natural conditions a severe bacteriemia does not occur in the resistant animal. Death with lung edema from anaphylaxis as seen in Sheep Nos.

	First Infection.	Second Infection.	Result.	Remarks.
Principals No. 71.	June 6, 1908, 1/10 mg. per 10 kilos, subcut.	Nov. 22, 1909, 1 mg. per 10 kilos intravenously.	Nov. 24, death from anaphylaxis.	Infection node pear-sized. Tuberculosis of shoulder glands and of mediastinal glands. No trace second infection. Acute edema of lungs, which are free of tubercle. Cheesy foci in udder.
	Jan. 4, 1909, 2/10 mg. per 10 kilos subcut.	.....	.....	Sheep No. 71 received also a subcutaneous injection of 2/10 mg. per 10 kilos body weight on Jan. 4, 1909, six months after the first infection.
No. 92.	Jan. 4, 1909, 2/10 mg. per 10 kilos subcut.	Nov. 22, 1909, 1 mg. per 10 kilos intravenously.	April 28, 1910, killed.	Infection node size hazel nut. Tuberculosis of shoulder gland, of liver, of tracheal, bronchial and mediastinal glands. Extensive lung tuberculosis.
No. 33.	Aug. 6, 1908, 1/10 mg. per 10 kilos subcut.	Nov. 22, 1909, 1 mg. per 10 kilos intravenously.	Still lives, healthy.	Had also injection of 1/100 mg. per 10 kilos body weight subcutaneously Sept. 20, 1906.
Control first infection No. 93.	Jan. 4, 1909, 2/10 mg. per 10 kilos subcut.	.....	Killed April, 1909.	Tuberculosis of subcutaneous glands of liver, of tracheal, bronchial and mediastinal glands. Moderate lung tuberculosis.
Control second infection No. 111.	.....	Nov. 22, 1909, 1 mg. per 10 kilos intravenously.	Dec. 20, 1909, died.	Both lungs thickly studded with tubercles. Shoulder gland and bronchial glands swollen. Other organs macroscopically normal.

Sheep No. 151, the control for the second infection, received the same dose of tubercle bacilli as Sheep Nos. 58 and 59 on July 7, 1911, and died on Aug. 25, 1911, of acute disseminated tuberculosis of the lungs seven weeks after the injection. Both lungs

71 and 58, illustrates the possible dangers of a too complete bacteriolysis. These animals were absolutely immune to reinfection with the large dose employed, but died, nevertheless, from the acuteness of their reaction to the tuberculous poison. That

this is the correct explanation is shown by the fact that the sheep that survived the severe illness with high fever which followed the large reinfection quickly regained their former health and when finally killed showed but slight tuberculous changes in the lungs. These were undoubtedly to be ascribed to the primary infection (note the calcified foci in the lungs of Sheep No. 33).

The demonstration appears to be complete that the more resistant animals of experiment are capable of acquiring an immunity as the result of the primary infection with tubercle bacilli, and that, too, when the first infecting dose is much greater than would be probable in natural infections, to enormous reinfections given intravenously. They were more than abundantly immune to any possible infection that could be received from without under natural conditions of infection. Römer could not detect any material difference in the reaction of his naturally infected guinea pigs to reinfectien as compared with those artificially infected. Still, there is a difference in natural infections which should in fairness be stated. It is this—when the naturally infected organism has come to contain many tubercle bacilli the fault is in part its own. There would not have been so large a number of its foes if it had been capable of acquiring more rapidly a strong resistance. The question then that we have to consider is, does feeble resistance within mean also feeble resistance to what of infection may come from without or, notwithstanding the too feeble resistance to growth of the already acquired lesions, has that organism nevertheless, developed a resistance sufficient to prevent outside infection so that it is on an equal footing in that respect with the animal like some of Römer's sheep which have been given their first infection dose when in perfect health? As we see from the history of Sheep No. 92, the condition of the animal must make a difference in its resistance to infection, possibly also to reinfection, and it is altogether probable that the naturally infected guinea pig would not be able to develop the phenomenal resistance of Sheep No. 33, for example. It is another question, however, whether the naturally infected animal or man does not develop sufficient immunity to become safe from natural infections from without. So far as the guinea pig is concerned, the question would appear to be answered by the resistance of the naturally infected animal to severe reinfection from the caseous matter from its own tuberculous gland as well as to large doses of tubercle bacilli derived from cultures; but we are especially interested in the tuberculosis of man and must, therefore, consider carefully the facts of human tuberculosis which may throw light upon this question. We inquire, then, does the human subject manifest the same resistance to tubercle bacilli, whether introduced from without or circulating in the blood from his own lesions as the animal of experiment? The answer to this question must be reserved for a subsequent paper.

THE SPLENIC REFLEXES OF ABRAMS IN THE TREATMENT OF SYPHILIS.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO, CAL.

"Once syphilis, always syphilis," and "Syphilis sleeps, it never dies," have achieved the importance of truisms to the phraseologist. My observations do not justify this prognostic pessimism; on the contrary, it is now possible in most instances to eradicate syphilis from the organism, if one may accept the electronic reaction' as a criterion of such eradication. In all sciences, the exposition of phenomena is incomplete, and practical and scientific theories are mandatory. The practical physician is entitled to ignore the writer's conceptions, but he can at least execute the simple therapeutic method and formulate his conclusions based on the therapeutic results.

Syphilis is one of the greatest human problems, destined to be accentuated by war conditions. For the present, at least, it is not suggested in the presence of acute luetic symptoms to substitute the writer's method for the conventional treatment, but to employ it in latent syphilis, and *always* as an adjuvant in association with the accepted therapeutic methods. By his method, unaided by medication, he has observed the return of lost reflexes which had persisted despite intensive treatment.

Conventional Medication.—This, it must be conceded, is often efficient in subduing acute luetic symptoms, but it is manifestly inefficient in totally eradicating the disease. The obituary of conventional syphilotherapy will be indited when nature's methods of cure are recognized and executed. The writer sincerely believes that the spleen as an organ of defense has not received due consideration by the clinician or bacteriologist. A clinical study of this organ suggests its basic importance in the *vis medicatrix naturæ*, not only in syphilis but in other diseases. The syphilographer questions the spontaneous curability of syphilis, but does not doubt complete recovery from medication. Respecting the former, there is some reason for contention; respecting the latter, there is none. The electronic reactions show that despite the duration of the disease, and however intense and prolonged the treatment, a reaction can always be elicited. Despite the most energetic specific treatment, one is often unable to convert a positive into a negative Wassermann. Reinfection cannot be accepted as an evidence of cure, for immunology shows that immunity produced by an infection is relative and not absolute, since it may be overcome by a more virulent form of the same infection. We know practically nothing about syphilis immunity, and are equally ignorant concerning the systemic reactions incident to infection with the *Spirocheta pallida*. "In syphilis, resistance to reinoculation, although high, is not absolute. The relative infrequency of true reinfection is due to the relative scarcity of completely

cured cases" (Zinsser). Zinsser admits that it is impossible to gather data showing the spontaneous cure of syphilis (without medical aid), and immunity to reinfection is an evidence of persistence of the disease in a latent form.

Gottheil, in a measure, summarizes his therapeutic nihilism concerning syphilotherapy as follows: "With mercury alone we apparently could cure syphilis; with mercury plus salvarsan we can do it better. We cannot do it with salvarsan alone."

Bacteria are complex proteins, and infection by them is practically a mixed infection. The accepted specifics do subdue one component of the infection, but no consideration is accorded to the components constituting the strains. Hence the relative insufficiency of treatment in syphilis. My reactions show that the only mercurial preparation subduing all the strains in syphilis is mercuric biniodide. This drug may be used by intragluteal injections without any harmful effects.

It has been demonstrated empirically that certain salts of mercury are more efficacious than others. This is quite understandable. Thus, in congenital syphilis, three reactions are evocable by the electronic reaction. The general reaction peculiar to the acquired and congenital forms is subdued by mercury and arsenic, but the congenital reaction is only dissipated by iodine, or a salt of mercury containing it.

Electronic Reactions.—These furnish the following information: (1) Whether syphilis is present or absent; (2) if present, whether it is congenital or acquired; (3) what tissues are or will become invaded; (4) demonstration with mathematical precision respecting the intensity of the disease; (5) whether the disease is quiescent (by measurement) or active; (6) whether a definite symptom-complex in a syphilitic is or is not dependent on syphilis.*

The electronic reactions have repeatedly been confirmed by competent observers.[3] Thus, Jarvis[3] asseverates: "The test of Abrams (electronic test) is positive in nearly 100 per cent. of syphilitic infections, whether hereditary or acquired."

The Wassermannic Menace.—The Wassermann test is the fetishistic *ignis fatuus* of syphilodiagnosis. It tells you that it is not syphilis when it is, and that it is syphilis when it is not. This is tantamount to saying it isn't when it is and is when it's not. The literature teems with unreliable reports respecting the Wassermann reaction. In any event, the reaction is not pathognomonic but monosymptomatic, and, whether positive or negative, its interpretation must be associated with laboratory tests, clinical signs, and therapeutic results.

This serological method is discountenanced, as is evident from the following: "A positive Wassermann unsupported by clinical evidence is not sufficient evidence of the presence of syphilis" (Keyes).

"Errors in the diagnosis of specific diseases of the nervous system were no greater in the pre-Wassermann days than at the present time" (Weisenburg).

There is only one chance in five that a specimen of blood submitted to ten serologists will result in an agreement. Collins estimates that 15 per cent. of cerebrospinal syphilitics fail to give a positive Wassermann in the spinal fluid.

One of the most serious and almost tragic arraignments suffered by the Wassermann emanates from the recent report of Symmers, Darlington, and Bittmann.[4] The report is based on nearly 100,000 reactions made by the most competent serologists procurable. Their conclusions are briefly as follows: (1) The reaction executed in the living patient at the Bellevue Hospital gives a negative result in from 31 to 56 per cent. of cases in which the characteristic anatomic signs of syphilis are demonstrable at necropsy. (2) The reaction in the living patient is positive in at least 30 per cent. of cases in which it is not possible to demonstrate any of the anatomical lesions of syphilis at necropsy. There is a vast difference between a culture tube and a patient and between the laboratory and the bedside. The aim of all medical service is the healing of the sick, hence the prestige of the therapeutic test, which recalls the aphorism, "*Naturam morborum curationes ostendunt.*"

"Who shall decide when doctors disagree, and soundest casuists doubt, like you and me?" In despair, we must hearken to the practical clinician. In a contribution on "Syphilitic Bone and Joint Lesions," Fisher emphasizes the frequency of negative Wassermann reactions in undoubted cases of bone syphilis, and in desperation maintains that the most reliable test of syphilis is the therapeutic test, thus reverting to the preserological period, when the nature of a disease was revealed by the effected cures. The disputants[5] of the paper are somewhat skeptical, to say the least, concerning the value of the Wassermann, and express themselves as follows:

"The diagnosis (syphilis) has to be made by instinct in many cases, instead of positive clinical facts." (Ridlon.)

"The only reliable test is the therapeutic one. One has to go back to the dictum of the pre-Wassermann clinicians, and say with them: 'When in doubt treat for syphilis.'" (Watkins.)

"There is no reliable test for joint syphilis. The Wassermann test, the Roentgen ray, the clinical course, the history, must all be considered, and we are not certain about our diagnosis." (Ely.)

"The negative results with the Wassermann are fully 50 per cent.; so we do not, as a rule, rely on this test, but look for other essential points." (Horwitz.)

Ubiquity of Syphilis.—"Know syphilis," observes Osler, "in all its manifestations and relations, and all other things clinical will be added unto you." The ubiquity of syphilis emphasizes the dictum of Fournier, that general pathology should be made a mere annex to syphilography.

The German diagnostician avers: "Was man nicht diagnostieren kann, Sieht man als n' syphilis an." Without a literal translation, the latter may be expressed as follows: "When your diagnosis goes amiss, always think of syphilis. It was said of Ricord, who was a confirmed skeptic as to the morality of the race, that he would have submitted Diana to treatment with his mineral specifics and prescribed a course of blue pills for the vestal virgins.

It is in the recognition of congenital syphilis

*The writer has just completed an apparatus enabling him to visualize the results. Heretofore, the reactions were dependent on human and animal reflexes.

that the greatest diagnostic acumen is demanded. We may not be civilized, but we certainly are syphilized. When the voltage of the radioactive energy of the blood of any individual is augmented about 1300 per cent. by an induction coil, the reaction of congenital syphilis can always be elicited by the electronic reactions. Such cases are usually without manifestations of any kind, but under certain conditions, as we shall learn later, when the virus is expressed from the spleen into the circulation, periodic symptoms develop, known under a variety of names—hemicrania, attacks of hysteria, epilepsy, nervousness, asthma, etc. It is a common belief that all diseases with a definite periodicity are malarial, but there are a host of diseases in which malaria can be excluded. When the blood is tested in the usual way by the electronic tests, without augmentation of energy, the ubiquity of congenital syphilis is, nevertheless, appalling. An analysis of 1,000 specimens of blood forwarded to my laboratory demonstrated the reaction of congenital syphilis in 45 per cent. of the specimens, in contrast with only 18 per cent. of the acquired form of the disease. My tests show that there is a synchronism of congenital and acquired syphilis.

Kaskell (quoted by Jarvis[5]) observes that while a positive Wassermann reaction can be elicited in about 40 per cent. of the wives of paretics and tabetics, yet only a small percentage of their children yield a positive reaction to that test. Stoll observes that in "late" hereditary syphilis the patient may present no sign, but a single obscure symptom may result in complete invalidism. Fournier observed that 98 per cent. of the children of syphilitic parents are syphilitic.

In Hochsinger's observations, embracing 208 children of syphilitic parents, 43 per cent. had some affection of the nervous system. Syphilogenic diseases do not yield such clear clinical entities as paresis and tabes, and "clinical pictures of a disease are largely literary efforts, and the product mainly of the descriptive art."

Cure of Syphilis.—The conventional medication for spirochetal poisons will be disregarded. An understanding of the writer's method predicates some knowledge of immunity, splenic functions, and splenic reflexes.

Immunity.—Drugs are mere incidents in the treatment of the sick. Neither the internist nor the surgeon can arrogate to himself the cure of disease, for recovery or death ensues despite medication. In pneumonia, the cures are effected by nature, and if 75 per cent. of the patients recover and 25 per cent die nature is 25 per cent. inefficient in the cure of pneumonia. To remedy this inefficiency on the part of nature necessitates a more thorough comprehension of immunology. Pathogenic organisms may be present on or in the organism without concomitant disease. When the organism is invaded by microorganisms a struggle for supremacy exists between the host and the parasites, and in this interaction the aggressive (parasites) contend with the defensive forces (host). At one time it was supposed that the phagocytes constituted the main defensive armament, but later the neutralizing substances in the body fluids were regarded as equally important. Still later a reconciliation was effected of the cellular and humoral doctrines.

The defensive mechanism of the organism consists essentially of the formation of a neutralizing antibody (antitoxin). The exact localization of the antibody-forming cells and tissues is not clear, although the preponderance of evidence suggests their origin in the lymphatic organs, bone, marrow and spleen. Zinsser[3] observes: "Splenectomized guinea pigs show no difference from normal animals in their susceptibility to tuberculosis. These and similar experiments have no great significance, since our knowledge concerning the true function of the spleen is very incomplete, and it is not impossible that on removal of this organ other elements of the lymphatic system may take over its function in part or as a whole." We shall learn later that a study of clinical physiology and pathology yields abundant evidence in favor of the spleen as the essential defensive viscus. The chemical composition of the spleen shows the presence of many albuminous bodies. It has been shown in the therapy of infectious diseases that not all the effects of injections of bacterial proteins were essentially specific. In other words, proteins and protein derivatives of many sources were as efficient as the specific antigen. It is also well to recall the action of serum and leucocyctic enzymes in the spleen as factors in immunization.

Splenic Functions.—No definite results concerning this enigmatical organ of the physiologist, despite experiments, have been evolved. Its removal from animals is not associated with any appreciable effects on normal metabolism. To deduce from this that its function is not very important would be equivalent to saying that the removal of one kidney is likewise not attended with appreciable effects. After removal of the spleen, compensatory functions are assumed by enlargement of lymph glands and augmented activity of the red marrow of the bones. Theories lacking confirmation have been proposed, but from this confusion two functions are associated with this organ, viz.: production of leucocytes and destruction of useless red corpuscles. It contracts and expands synchronously with the digestive periods. In its contractions it loses 18 per cent. of its volume. The volume changes are akin to the peristalsis of the gastrointestinal tract, and are caused by rhythmic contractions of the smooth muscle tissue in the capsule and trabeculæ. The diminution in volume (systole) and volume increase (diastole) occupy together about one minute. In addition to these rhythmic variations it increases in volume for a period of 5 hours after digestion. It is the popular belief that the spleen is influenced by the nervous system, and Botkin asserts that depressing emotions increase and exhilarating ideas diminish its volume.

Experimentally, the physiologist can by stimulation reflexly contract or dilate the organ. The writer has shown[7] that reflexes may be elicited and demonstrated with the same certainty in the living human subject as is done by the vivisectional experimentalist. This phase of medicine has been called "Clinical Physiology" by the writer, and suggests that human and not animal physiology should be the basis of clinical pathology. Clinical physiology enables one to elicit many data concerning

the spleen which are beyond the ken of the physiologist.

Splenic Reflexes.—The visceromotor centers in the cord may be stimulated so that one may at random either contract or dilate the spleen. These reflexes* are known respectively as the splenic reflex of contraction and dilatation. In the norm, the reflexes are of short duration (not in excess of 2 minutes), and in their objective demonstration by radiodiagnosis† and percussion one must expedite the latter maneuver. It has been determined empirically that the elicitation of the reflex of contraction is effected by concussion of the second lumbar spine and the counter splenic reflex of dilatation by concussion of the eleventh dorsal spine. A plexímeter is placed on either spinous process and then struck a series of moderately vigorous blows with a plexor.

Reflexodiagnosis and Reflexotherapy.—The reflex of contraction is employed in the treatment of splenomegaly. In latent malaria, one may precipitate a typical paroxysm by discharging the splenic reflex of contraction (concussion of the second lumbar spine). It is assumed that the paroxysm is provoked by the mechanical extrusion into the circulation of the plasmodia which have lodged in the organ.

In suspected malaria one may find plasmodia in the blood after evoking the reflex of contraction, even though absent before this maneuver is executed. Hematological investigations by the writer show the following: (1) Average increase of erythrocytes after concussion of the eleventh dorsal spine (which increases the splenic volume) 300,000, and an average increase of hemoglobin of 5 per cent.; (2) average leucocyte increase after concussion of second lumbar spine (decreases splenic volume), 2.800; (3) average increase of red cells after alternate concussion of second lumbar and eleventh dorsal spines, 650,000 with an average hemoglobin increase of 10 per cent.

The employment of this reflex in a symptomatic and therapeutic direction is of great value. My experience with the reflex of contraction permits me to conclude that if in a suspected case of malaria typical or atypical symptoms of the disease do not supervene after elicitation of the reflex in question the disease is not malaria. Similarly, suspected symptoms of syphilis are often accentuated after the same maneuver. Take a typical case of acquired syphilis and measure the syphilitic energy from the spine, liver, and spleen, and we have the following figures: spine, 6/25; liver, 23/25 of an ohm; and spleen, 1 ohm and 10/25 of an ohm. Immediately after concussion to elicit the reflex (the patient is undergoing mercurial treatment), the reactions are as follows: spine, 1 2/25; liver, 12/25; and spleen, 18/25. Thirty minutes after evoking the reflex: spine, 1/25; spleen, 22/25.

The elicitation of this reflex of contraction causes a hyperleucocytosis. It has been shown experimentally that intravenous injection of splenic extract evokes a like condition. Wells has shown that the splenic pulp contains the greatest number of leucocytes (in one instance 180,000 per c.mm.). This concentration is evidently the result of the fixation in the spleen of the presence of the products of disease which exert a positive chemotactic influence toward the leucocytes. Evocation of the splenic reflex of contraction is, in my opinion, one of the most valuable adjuncts in the treatment of infections. This applies not only to syphilis, reference to which has already been made, but to streptococcic and gonococcic infections. Although the organisms of these diseases may be absent in the blood, their presence in the latter may be shown after elicitation of the splenic reflex.

The localization in the spleen of the toxins of different infections makes practically a "dead corner," and resists drug action, demanding daily elicitation of the splenic reflex. The maneuver which excites this reflex also elicits the liver reflex. The liver is an important organ of defense, and detoxicates toxins conveyed to it by the portal circulation. It is interesting to observe that Dr. William J. Mayo, in his Carpenter lecture at the New York Academy of Medicine (October 18, 1917), sustains my theory as follows: "Hibernation of spirochetes in the spleen permits luetic reinfection of the body."

The use of intraspinal and even intracranial injections of specifics based on the supposition that the permeability of the meninges and choroid plexus are impaired is wrong. Salvarsan and mercury, even though not given parenterally, may be demonstrated electronically from the spine in a few minutes.

Elicitation of the splenic reflex of contraction is an important aid in evoking the Noguchi reaction when absent, and accentuating it if present. These findings have been confirmed by Frauchiger.

From an investigation of a comparatively large number of cases of syphilis, coupled with observations bearing on the results of treatment, we deduce the following:

1. The usual depositories for the luetic virus are the spleen and liver, notably the former.

2. When the splenic and liver reflexes of contraction are evoked by concussion of the second lumbar spine there is an immediate extrusion of the virus into the circulation.

3. The spleen is not a quiescent viscus, but undergoes periodic changes in volume.

4. Emotions, digestive disturbances, and other factors may precipitate extraordinary volume changes in the spleen, thus eliminating the products of the disease into the circulation, causing an exacerbation of symptoms present or producing them if absent.

5. In parasyphilitic diseases the parasites are found in the "dead corners" of the organism, and

*More fully described in Abrams' "Spondylotherapy," 6th edition, pages 251 *et seq.* and in the "Reference Handbook of the Medical Sciences," Vol. VIII, third edition.

†Careful fluoroscopic examination of the splenic reflexes show that (1) concussion of the eleventh dorsal spine augments the splenic volume; (2) concussion of the second lumbar spine diminishes the size of the spleen; (3) after the ingestion of bismuth, concussion of the eleventh dorsal spine increases the splenic shadow and that concussion of the second lumbar spine diminishes the density of the shadow. The increased shadow effect is probably due to the bismuth aspirated into the spleen and not to increased density of the organ, as there is less density in an enlarged than in a contracted spleen. The latter view is sustained by a few experiments by the writer on animals. After an injection of methyl blue, more dye is found in the spleens of animals when the splenic reflex of dilatation is executed than in control animals.

resist the action of drugs. Similarly, virus lodged in the spleen is equally resistant. Elicitation of the splenic reflex is therefore a valuable adjunct in syphilotherapy. The same fact applies in all cogency to other infections and in a number of diseases, notably "fatigue neurasthenia."

Splenic Reflex of Dilatation.—Chief consideration has heretofore been accorded to the counter reflex of contraction, and while elicitation of the latter has given the writer material aid in rapidly reducing (in conjunction with medication) syphilis from an active to a quiescent state, it has never effaced a positive electronic reaction of the disease. It was not until *both* reflexes were employed that one could positively eliminate the reaction, and this was attained without synchronous treponemicidal medication.

Contraction of the spleen mobilizes the luetic virus by eliminating it from the spleen. The reflex of dilatation is a process of scavengerism, centralizing the toxins in the spleen from every cranny of the organism.

Thus the electronic reaction from the spleen in a syphilitic shows a luetic reaction of 5 ohms and 4/25 of an ohm. After concussion of the second lumbar spine (splenic reflex of contraction) it measures 5 25 of an ohm, and after concussion of the eleventh dorsal spine it measures 15 ohms and 4/25 of an ohm. Mensuration from the spine shows an increase in the potentiality of the reaction after concussion of the second lumbar spine and an absolute annihilation of the reaction after concussion of the eleventh dorsal spine. This annihilation is only temporary, but after a persistence of the method it becomes permanent. When the reflex of dilatation is elicited one is practically executing a vacuum therapy, and when the counter reflex is excited an elimination therapy. This process is not unlike the action of a suction and force pump. The physiological mechanism of suction is expressed in sucking, and in suction of the thoracic cavity and heart. "Self-massage of the heart," as Brunton[m] puts it, is an analogous condition whereby nutrition of the heart is largely dependent on its own activity. The pericardium is like a bell jar. When the ventricle contracts, a vacuum is produced in the pericardium, thus sucking blood into the auricles and ventricles and from the blood and lymph vessels. The therapeutic action of digitalis is largely dependent on the fact that it aids or augments the natural suction power of the heart.

Quinine* yields, by virtue of its radioactive energy, a specific area of abdominal dullness. When ingested and a reaction is taken from the spleen after a lapse of time, no reaction of quinine from the spleen can be evoked. Elicitation of the splenic reflex of dilatation, however, will, after the lapse of a minute, enable one to elicit the reaction from the spleen. The splenic reflexes may be demonstrated by percussion and in suitable cases by the *x*-rays. Expert percussion enables one to determine contraction of the spleen every 3 or 4 seconds, but there is no volume increase.

When any of the drugs used in syphilis are presented to the splenic region, percussion shows a slight alternate increase and decrease in the volume of the organ at regular intervals. This change in volume, however, is infinitesimal compared to the volume change evoked by concussion.* The foregoing permits one to conclude that spirochetal drugs may act by provoking volume changes in the spleen.

Hematophagia.—This term suggests itself in referring to a therapeutic procedure known as "autohemic therapy," developed by Dr. L. B. Rogers of Chicago. It consists of giving the patient a solution made by attenuating, hemolyzing, thermolyzing, diluting, and potentizing a few drops of the patient's blood and administering it according to a definite technique. Empirically, this method finds justification by the results achieved by many enthusiastic devotees of the method who are less concerned with its scientific than its therapeutic value. Insomuch as this method is related to the immunologic methods of the writer, brief reference to it will be accorded.

Dilution, as the writer has shown, augments the dynamic action of drugs and antibodies. The writer found that if a neurasthenic will ingest a few drops of his own diluted blood it will temporarily dissipate his electronic reaction of neurasthenia, but the same blood given to another neurasthenic is without influence on the reaction. A similar observation has been noted with syphilitics. The radioactive energy of the normal spleen dissipates the reactions of the streptococcus and staphylococcus, colon bacillus, tubercle bacillus, and typhoid bacillus, but is without effect on the carcinomatous reaction. The latter is dissipated by the radioactive hepatic energy. To secure more permanent action, it is suggested by the writer to evoke primarily the spleen reflex before removing the blood. It is likewise suggested to observe results per os without recourse to parenteral methods.

The writer often demonstrates to his classes an electric phenomenon incident to the elicitation of the spinal reflexes. A proof plane held in contact with the skin adjacent to a concussed spinous process will show a negative electric charge when transferred to the knob of an electroscope.

In an editorial in a recent number of the *American Journal of Electrotherapeutics and Radiology* (July, 1918), reference is made to the fact that spinal stimulation to evoke the visceral reflexes will effect cures where drug medication utterly fails.

Splenotherapy.—The execution of the writer's method for the treatment of syphilis is as follows: Locate the 11th dorsal and 2nd lumbar spines and mark with a pencil of silver nitrate or skin ink.† Provide the patient with either to reapply, should the marks become effaced. A strip of plaster may also be used but it is usually removed in bathing. Methods for counting the vertebral spines in obese subjects must be employed. When there is any doubt respecting localization, note that if one concusses the 2nd lumbar spine, percussion (executed immediately) shows a reduction of the splenic volume, and conversely an augmentation is found after

*Bioclinical reactions in toxicology are discussed in "New Concepts in Diagnosis and Treatment," p. 288.

*The action of grosser methods of stimulation of the spleen is noted on p. 354 in "Spondylotherapy."

†A relatively efficient ink is as follows: Acid pyrogallic, 1 gm.; acetone, 10 c.c.; liq. ferri perchlor. fortior., 2 c.c.; spirit. vini meth. ad. 20 c.c. Brownish at first, it becomes black after several hours. Application should be preceded by removal of fat from the back by ether.

concussion of the 11th dorsal spine. Some relative or friend may be entrusted to execute concussion twice daily. A tack hammer and a cork suffice for this object. The concussion is first executed at the 2nd lumbar spine and then at the 11th dorsal spine. The cork is firmly fixed over the spines and light blows are executed. The entire duration of treatment is 6 minutes; 3 minutes devoted to each spinous process. The 3 minutes' treatment is discontinuous, being made up of concussion for one-half minute with intervals of rest for the same duration of time to avoid exhaustion of the reflexes. *When this treatment is conscientiously pursued for about 2 weeks, one can no longer, as a rule, elicit an electronic reaction of syphilis and this result is achieved exclusively by the reflexes without coincident medication.*

Concussion of the 2nd lumbar spine also elicits the liver reflex of contraction, and it may be noted that examination of the urine before and after concussion shows increased indican excretion after concussion as well as ethereal sulphates and urea.* An immediate effect of the treatment is the improved color of the patients owing to the hematogenic action of the splenic reflexes. Another conspicuous effect in neurasthenics is the betterment of the sexual vigor and other symptoms. The beneficial effects may be attributed to the reflexes which centralize the fatigue toxins in the spleen and then excrete them. After elicitation of the splenic reflex of dilatation, the electronic tests of neurasthenia evanesce.

In conclusion and parenthetically, without any concession to the value of the Wassermann reaction, it was noted in 5 cases, where this reaction had persisted despite intensive treatment, that it became negative subsequent to the execution of the writer's method of treatment.

BREATHING GYMNASTICS FOR THE MARCHING SOLDIER.

BY N. J. POOCK VAN BAGGEN.

THE HAGUE, HOLLAND.

UNTIL quite recently breathing gymnastics were only and specially used by vocalists and by sufferers of different affections of the chest, as asthma, bronchitis, emphysema, etc.; but also in respect to this the war has brought a change.

The training of the physical force of the soldier attracted of course our full attention, and it seemed to us that breathing gymnastics could be of great value to them. The development of the chest, the strengthening of the muscles of the thorax, and the fortifying action of the breathing exercises on the pulsation of the heart are evidently of great advantage for those who are obliged to exert their physical capacities to the utmost.

Experience showed us, moreover, that the control over the breath, which means the regulation of inspiration and expiration, is most valuable while walking, marching, running, and in general while performing any bodily exercise.

Our opinion as to this matter found agreement with the commander-in-chief, charged with the physical development of the soldiers and, for a first experiment, fifty men were put at our disposal. The object we had in view was to know if the results paid for the effort and the time expended.

We began with an exact investigation of the breathing power of each man separately. This investigation comprehended the examination of the form of breathing (clavicular, costal, or diaphragmatic), the power of expansion of the chest (shown by the difference in circumference of the chest after a full inspiration and an entire expiration), and the length of the period of exhalation.

As to the form of breathing we found that in all the fifty cases, without one exception, the breathing was clavicular. Now in the case of clavicular breathing we expand in inspiration the upper part of the chest. For executing this movement we must raise the collar bones and with them the arms, the shoulder blades, and the upper ribs; the latter are attached in the back to the spine, and in front to the sternum, thus all inflexible unyielding parts. It is clear that this demands a great effort, the result of which is that the amount of breath we inhale in this way of breathing can be but small, because the apices of the lungs, that is the narrowest part of them, only will be able to dilate to their full extent, while the expansion of the larger and stronger part of the lungs is reduced to the minimum. By this mode of breathing it is also impossible properly to control expiration. After having raised with great effort those inflexible parts of the chest, a much greater effort must be expended out to keep the thorax a moment in this attitude and then contract it slowly as is required for a properly managed expiration. Thus we must condemn in every respect the clavicular breathing and we must do this particularly in the case of the soldier, especially as this form of breathing is further hindered by the straps of his kit and the gun on his shoulder. By teaching him another mode of breathing, whereby the shoulders and the upper part of the chest remain almost without movement, he will be greatly relieved and his burden will be carried with much more ease.

The lower part of the chest is formed by the floating ribs, and the base by the diaphragma, all flexible and easily yielding parts, the contraction and relaxation of which will be effected without much effort and for a great length of time without causing much fatigue. The lungs being largest at their base, the amount of air we inhale by expanding the lower part of the chest will be greater than when the upper part of the lungs is chiefly inflated.

The advantages of the low breathing are evident and what is more the so-called low breathing is

*Spondylotherapy, 6th ed., p. 336.

the natural way of breathing. The newborn baby moves, while breathing, the lower part of the chest, and generally the very young child breathes low. We have not yet been able to state what are the real causes of clavicular breathing being so frequent. By most of our grown-up pupils in breathing gymnastics the breathing is clavicular. However, the low breathing being the natural mode of respiration, but little difficulty is experienced in teaching them this method and in making them adopt it. Generally it takes two or three lessons to place (as we call it) the breath. We begin by teaching a purely diaphragmatic breathing and when this offers no more difficulties to the pupil, we develop this method in another which is a combination of clavicular, costal, and diaphragmatic breathing, on the understanding, however, that the diaphragmatic and the costal breathing predominate and that there is but a very slight movement of the upper part of the chest. This combination of the three methods allows the chest to enlarge to its full capacity. We then apply a series of exercises to strengthen the muscles of the thorax and to make them supple, aiming also at a large expansion of the chest during inspiration and a greater contraction during expiration.

At the first examination of those fifty men we found that on an average the expansion of the chest amounted to from 3 to 3½ inches. After four weeks' exercising the average expansion had risen to from 5 to 6 inches. We found also that the exercises had an excellent influence on the correct erect bearing of the men.

After a fortnight's exercising we began to teach the control over expiration and inspiration; first while standing still, then marching, and finally marching at double-quick time. Also the control over the breath while performing other gymnastic exercises, as jumping, throwing, etc., was made part of the teaching. We continued teaching the exercises during a month. Twice a week we led the course personally, the other days the men exercised under supervision of assistants. At the end of the course we also gave the men instructions how they best could fight the disastrous results of poison gas and how they could help each other in these cases by appropriate breathing exercises.

The results of the practice were most satisfying. The men not only liked the exercises and did them with pleasure, but they also became conscious of the advantages of the new method of breathing. Especially during long marches the regulation of expiration and inspiration proved to be most efficient.

Several of the men told me that they used some of the exercises after trying marches by way of a refreshment. A long and deep breathing exerts in fact a revivifying influence. After strenuous exertions the great consumption of vital energy demands nourishment not only of effectual food but of oxygen to clean the blood of the exhausted elements.

After this first experiment we tried a second with a hundred men which met with a still better success, so that the commander-in-chief ordered the breathing gymnastics to make part henceforward of the exercises prescribed for the general physical development of the soldier.

PNEUMONIA, ACUTE EMPYEMA, ACUTE APPENDICITIS, PNEUMOCOCCIC PERITONITIS, THEIR DIFFERENTIAL DIAGNOSIS.*

BY MOSES BEHREND, M.D.,

PHILADELPHIA.

THE seasonal occurrence of pneumonia and empyema is at hand. While all may occur at any time during the course of the year it is important that one be alert especially on account of the recent epidemic of influenza with its accompanying high rate of mortality among the flower of the country. During this epidemic while the infection was a general one the respiratory tract suffered most. A reminder at this time of the distinguishing features of the chest versus abdominal conditions would seem to be profitable to many of us.

Let it be understood at the beginning that there are many cases where it is impossible to make an absolute diagnosis between the two. The citation of cases later will illustrate this point. It requires very close observation of the young patient although adults often present the same difficulty in diagnosis. The cooperation of the physician and surgeon and often the radiologist is necessary to arrive at an ultimate diagnosis. Notwithstanding all the fine accessories which now enable us to make more accurate diagnosis, still mistakes will occur, pneumonia being operated upon for appendicitis and often cases of appendicitis being treated for pneumonia and acute empyema, the latter circumstance being fraught with more danger than the former. Acute purulent pleuritis has been placed in this discussion although the writer has not encountered this disease as a primary one. All the cases of empyema that have come under my notice have been secondary to pneumonia. Osler speaks of it as occurring in 32 per cent. out of a total of 252 cases. The disease is a rare one but may at times be mistaken for an acute appendix.

It might seem superfluous to give before this body of general practitioners the symptoms of these diseases, yet a review may be of service in discussing the cases that will be presented to illustrate this paper.

It has been stated that the mistakes usually occur when children are the sufferers. Pneumonia may occur at any age of infancy or childhood and the younger the individual the more difficult will it be to make a proper differential diagnosis. Probably the one distinguishing point on inspection between pneumonia and appendicitis in childhood is the rapid breathing and the playing of the alæ of the nose. The temperature may be higher in both diseases but it is usually higher in pneumonia. Appendicitis is rather rare in infants but the youngest demonstrable case that the writer has operated on was in a baby nine months old.

Physical signs in the chest must assist in the diagnosis, but we lay considerably more stress on inspection than on any other physical sign in the differential determination of the disease.

*Read at a meeting of the Alumni Association of Mt. Sinai Hospital.

There is only one exception to this observation when rapid breathing will lead one astray, namely, in that rare condition known as pneumococcic peritonitis.

As the child grows older and is able to give more detailed expression to his symptoms one will find that in pneumonia pain is often referred to the right side of the abdomen. Rigidity along the rectus muscle is often marked. Here again inspection is an important physical sign. The child with pneumonia is restless with a bright flush on his cheeks. The temperature is high at the beginning. In appendicits there may not be a rise of temperature. The signs on auscultation and percussion are of little assistance because in these early stages the disease has not progressed sufficiently to elicit signs. The *x*-ray will not be helpful at this stage of the disease.

The leucocyte count will be high in both diseases but it is usually higher in pneumonia. It is not unusual however to have a leucocytosis of 20,000 or over in appendicitis. It would be wise in the differential diagnosis of these conditions to disregard the blood count altogether. I do not wish to be understood that the blood count should not be taken; routinely it ought to be done, but too much stress must not be put upon determining the nature of the diseases from the degree of the leucocytosis.

Although the difficulty in differentiating chest from abdominal conditions preponderates in children, the same applies in a measure to adults. A colored man was admitted to the service of Dr. Shmookler with symptoms simulating appendicitis on account of intense rigidity of the right rectus muscle. This was, however, his sole abdominal symptom. Upon close observation we noticed that he was breathing rapidly, the alæ of the nose were distended. We ruled out appendicitis and later observation and examination showed he had pneumonia. Several weeks later I operated on him for empyema and abscess of the lung. He died from toxemia some months later.

The writer does not remember ever having seen a case of primary or acute empyema although, as noted before, Osler has had 32 per cent out of 252 cases, still it must be considered a very rare condition. In a child when a case difficult of diagnosis presents itself it seems to me that we ought to think of the most common condition rather than of those rare and unusual affections primarily. It has always helped in cases of doubt between appendicitis and chest conditions to operate and remove the appendix. Before doing this, however, if one is not certain an aspiration of the chest will assist in making the final diagnosis as to whether fluid is present. Aspiration is practically harmless under aseptic conditions. In my opinion the aspirating needle is not used frequently enough because of some timidity on the part of the general practitioner. This fear is groundless because after the use of the needle innumerable times no harm has ever resulted from its employment. A Luer syringe is not the best diagnostic method; the aspirating set being far superior and more positive in its results. In those cases in which I was mistaken the removal of the appendix had no effect on the pneumonia, the crisis occurring as usual without further complications. In cases of doubt nitrous oxide gas and oxygen is the best anesthetic.

Pneumococcic peritonitis was given close consideration by Parker Syms. This is the one instance in which, to my mind, it is absolutely impossible to make a diagnosis between pneumonia and appendicitis and the condition under discussion. The reason is that one gets all the symptoms of pneumonia in pneumococcic peritonitis. The rapid respirations with anxious expression, the one sign on which we place most stress, is prominent in this disease. The abdomen is excessively rigid all over with the signs of general peritonitis. This disease is in the true sense of the word an abdominal pneumonia.

An interesting fact in this connection is the admonition of most writers on the subject not to operate immediately on these cases. The object is to wait until the pus becomes localized and then evacuate it. This contingency causes more difficulties in the diagnosis which one could readily understand if the peritonitis were due to an appendicitis. The history and primary physical signs would be of some assistance. By this I mean there would be in a pneumonic peritonitis general rigidity and tenderness, while in appendicitis one would get the initial pain and tenderness in the right side. Girls are most frequently affected, the avenue of infection being the vagina.

It seems superfluous to call your attention to the symptoms of acute appendicitis, but in the consideration of these related diseases a brief review may not be amiss. In appendicitis the symptoms usually come on suddenly; general abdominal pain being followed by vomiting is the most prominent symptom and the first to appear. General abdominal tenderness and then localized pain and rigidity are noted in the right iliac fossa. Unless the pain is very severe there is usually no interference with the respiratory rate.

A case of exceptional interest to illustrate the difficulty in the diagnosis of pneumonia and appendicitis is the following:

> A child, twelve years old, had a typical attack of pneumonia two years ago. The diagnosis was not a difficult one, the patient having signs of pneumonitis on inspection at the very inception of the disease. Last year the child was taken suddenly with pain in the abdomen, located especially in the right upper and lower abdomen. No symptoms referable to the chest were present and physical signs could not reveal any pathology. The respirations were rapid, but we were so impressed with the intense rigidity and tenderness of the abdomen that operation was advised. Nitrous oxide gas and oxygen were given because I could not eradicate from my mind the one symptom of rapid respiration, which indicated to me that a possible pneumonia existed. While the convalescence was uneventful, the child passed through a typical course of pneumonia with the crisis on the ninth day.

To impress on you further the differential diagnosis between pneumonia and appendicitis I would cite the case of an unusually intelligent child admitted to Mt. Sinai Hospital with the diagnosis of appendicitis. The internist thought there was a possibility of pneumonia or acute empyema. In this diagnosis I could not concur because the child was breathing quietly, having observed him while asleep. He became irritable only while be-

ing examined on account of the pain induced. He had a high leucocyte count which influenced the internist not a little in believing that a chest condition existed. It seems this warning about putting your dependence on the leucocytic count must be frequently sounded by the surgeon. When there is a positive leucocytosis it is of some value but the degree of leucocytosis cannot be weighed for or against a lesion in certain parts of the body. A positive leucocytosis is of value in determining the presence or absence of pus, but its absence or even a leucopenia does not mean that there may not be an inflammatory lesion present.

Another instance in which a pediatrist, internist, and surgeon figured will further show that the physician must be careful to differentiate chest from abdominal conditions:

A child, seven years old, was admitted to the Lebanon Hospital, complaining of pain in the right iliac fossa. The internist and pediatrist could not agree as to the diagnosis. I was asked to decide the question. Careful inspection of the patient exeluded a chest condition. Palpation of the abdomen revealed rigidity of the right rectus muscle and tenderness. Operation was performed and a pus appendix removed, the appendix being surrounded with plastic lymph.

This recital of cases could be continued indefinitely but these illustrate the main points discussed.

In conclusion I would like to impress on you the fact that inspection is the most important physical sign in differentiating thoracic from abdominal conditions; that in cases of doubt the aspirating set should be used more frequently and always in preference to the Luer syringe; that when a mistake has been made operation has not interfered with the course of the pneumonia provided the proper anesthetic has been used.

1427 North Broad Street.

CHLORINE, DICHLORAMINE-T, AND CATGUT.

By R. F. OFRIAS, Phg.,

NEW YORK

PHARMACIST, KNICKERBOCKER HOSPITAL.

When Doctor Stewart asked me to make an independent experiment to determine the effects of the so-called dichloramine-T solution in contact with catgut there arose in my mind at once the very natural question of what is the use of wasting any time in making the necessary tests or in bothering about such a matter at all. For one must be a very tyro in or smatterer in his knowledge of chemistry if he is not well aware, in advance of any practical trial whatever, that of two contradictory factors one must be true. He should at the very least be able to draw one of two easy inferences, and should at once conclude that dichloramine-T either will or will not attack catgut. If it contain free chlorine it will attack, or if it does not so attack then it does not contain much free chlorine. The whole matter in question works out into a case of certain and assured destruction of the catgut, or else it is a case of misbranding of the goods contained in a bottle that was supposedly packed in good faith. To my way of thinking, it was all so simple, apparently, that it was but a question of correctness or incorrectness of the statements spread upon a label by printer's ink. If those statements were accurate, then, of course, the catgut would be destroyed if exposed to the solution described upon that label, for small practical experience in every-day chemistry would enable one to draw such a conclusion with certainty. Every washerwoman knows that Javelle water will attack her hands, and every fuller (linen-treader) knows that solutions of bleaching powder will attack his feet. But should any one desire to make the discovery for himself, he can obtain an object lesson from the very unpleasant character of chlorine dermatitis—a trouble which may be found following the wearing of new well-bleached, though unsoaked, undergarments that come into close contact with his own skin.

In view of the plain features of the outlook as just set forth, it is impossible for a chemist to understand or to comprehend why there should be any differences of opinion, or where there is left any room for discussion or for argument whatever upon a question as to whether or not chlorine will attack ligature material. Chlorine is one of the most active chemical agents, so much so that it combines readily with almost anything in its neighborhood; therefore, it is not found in nature in an uncombined or free state. Why should we not admit a truth that is based upon the experience of all students of chemistry, and acknowledge without cavil that if the presence of hydrogen be granted then chlorine will readily displace it, will then form hydrochloric acid or some similar destructive product, and its destructive activity will be exerted upon the animal, vegetable, or mineral kingdoms? Is it necessary now, at this late day, to quote the provision of the acid law or anti-acid law, or is it really necessary to repeat the bald archaic statement that the country round about an alkali factory, for miles and miles was once little better than a desert, where even the rain brought down its quota of HCl to attack and destroy albuminoids? The whole picture was once so dreadful that mandatory law was invoked to stop the conditions that obtained. In the face of all this consider that a catgut that does not contain hydrogen cannot be catgut, and a chlorine that will not replace hydrogen cannot be chlorine, and then let us plan some argument or set forth some reason, if we can, why catgut should not be attacked by dichloramine-T. Why not consider the positive statement a settled affair?

Rather to my surprise, Dr. Stewart took quite another view by voicing his idea that far from being a settled affair it was, in his opinion, of the most supreme importance not to the medical profession alone, but to the whole human race. Because, if catgut could be placed in a chlorinated solution, could at the end of ten days be converted into the usual amorphous state, and could be found at the end of three weeks to be in its original unchanged condition, then that experiment would be the pioneer laboratory proof of the physical resurrection of the dead. Because if any one tissue could be proved to have survived the diffusion of its elements then it might be quite easy to start from that point and to prove that all tissues could so survive. Whether this view be tenable or not need not detain us, nor need further time be wasted in discussing the tenability of the fact that chlorine

will attack tissue, living or dead. The sole question here set forth is how much destructive effect has a solution named dichloramine-T (or "Tea," in common hospital parlance) upon catgut that is submerged in that solution.

The first experimental fact that became apparent was that it was impossible to get regular and invariable results because there was such a wide variation in the resistance of different pieces of catgut, both when taken from different portions of the same roll, or skein, and when the products of different manufacturers were compared. Submerged in the usual aqueous chlorine solution, the daily loss of tensile strength of catgut was two pounds as a maximum and one pound as a minimum, with an average of one and a quarter pounds. It followed that the action of this solution upon dead tissue, both within wounds and outside of them, varied in a proportion that might be expected from the aforesaid. The solution was the same, but its age or the unknown resistance of the tissue made any exact calculation difficult. The specimens of catgut which were submerged in dichloramine-T showed a loss in tensile strength that varied from one pound per day to one pound per week, and against dead tissue within and without wounds it seemed no way comparable to the 2 per cent. aqueous solution.

Perhaps it may be well to state that chlorine in oils and in paraffin was tried out long ago without producing the least effect upon the standing chemical rule that chlorine shows its most marked effects with water. If one wishes the effect of this halogen he must use water, or if he wishes to blur those characteristic effects then he may use oil or paraffin. All the preparations of chlorine will destroy catgut, or if they fail in this the chlorine is not in an active state, or is in a valueless or spoiled environment that hampers chemical activity. To a chemist the deliberate employment of an inferior product is something that defies analysis, yet he who prefers to substitute dichloramine-T for the aqueous solution would appear to be doing that very thing.

The summary is that dichloramine-T will attack catgut, but in that and in every other sphere of chlorine activity it is inferior to an aqueous solution.

Medicolegal Notes.

Workmen's Compensation—Accidental Death by Arsenical Poisoning.—In a proceeding under the Illinois Workmen's Compensation Act for death alleged to have resulted from an accidental injury received in a zinc smelting plant the decision depended upon substantially the following facts: The deceased had worked at the plant for thirty-eight years, for fifteen years as a foreman at the furnaces. Each day he was required twice during his eight-hour period to work for about forty-five minutes in drawing the scum and dross, or oxide as it is called, from the surface of the molten zinc or spelter. For this purpose he used an iron rod about 15 feet long with a scraper on the end. He threw sal ammoniac on top of the molten spelter, and inserting the rod in the furnace, drew the scraper over the top of the molten metal, drawing from the surface the scum or dross, which fell on a platform in front of the furnace, giving off hot, burning gases, vapors and fumes until it cooled. There was a hood over the furnace, but it did not extend over the place where the oxide fell and did not take away the gas generated by it. In that work he was part of the time within four or five feet of the furnace door, and when the oxide was cold he shoveled it up and it was taken away. The ore smelted contained 99 per cent. of zinc, a fraction less than two-tenths of 1 per cent. of lead, and a trace of arsenic. The plant had been operated for nearly fifty years, and no case of lead, zinc, or arsenical poisoning had ever appeared there. The deceased during all his years of service had been in good health, with the exception of two accidents, which had no relation to his death. Two other men who worked with him had never been injuriously affected. On October 6, 1914, Tuesday morning, he began work at 6 o'clock, after being idle Sunday and Monday. On leaving home for work he said he did not feel like going to work. He worked until 2 o'clock in the afternoon, when he went home sick and had dysentery. This was first attributed to coffee he had drunk, but the attending physician found there was nothing the matter with it, and other members of the family who had drunk it were not affected. About 8 in the evening the deceased was seized with cramps through his arms, legs, chest, stomach, and bowels, and from that time he grew steadily worse. His discharges were black and loose. His teeth became black and loose, there was a dark line around his gums, his toe nails and finger nails became black, his eyes had a glassy, staring look, his wrists dropped, and his mind wandered. He was treated at home until October 12, when he was taken to a hospital, where he died on October 14.

The petition based the claim for compensation on the ground that he had absorbed such a quantity of lead that he was poisoned. Two doctors gave opinions as to the cause of death. One of them testified that the symptoms indicated lead and arsenical poisoning; that lead poisoning was commonly the result of a long course of absorption, and his conclusion was that the death was from arsenical poisoning alone. The other doctor gave an opinion that the death was due to arsenical poisoning, and said that usually such poisoning was not acute, but that arsenic is a cumulative poison, which accumulates in the system until it gets to a point where the poison springs into life and there is an explosion which is of an acute nature. He thought that probably the deceased's system became surcharged with arsenic which finally became acute arsenical poisoning, causing his death. The finding of the industrial board was that the death was due to acute arsenical poisoning not of a chronic nature, or a culmination of a gradual development of a long course of poisoning.

The defenses were that there was no evidence that any accident happened to the deceased; and that the death was caused by an occupational disease, which is not accidental within the meaning of the Illinois act.

The Illinois Supreme Court holds that there was evidence from which the industrial board was warranted in finding that on October 6, 1914, in the course of the deceased's employment, he contracted arsenical poisoning which resulted in his death. It was true he had been exposed to practically the same conditions for many years without injury, but it would not be unreasonable to conclude that his immunity was because of the state of his health and his ability to resist the deleterious effect of the gases and fumes over which he worked; but this time his physical condition was such as to make him susceptible to arsenical poisoning in such a degree as to bring on his fatal illness and death. As to the second defense the court said that for nearly fifty years in the active operation of the plant a case of lead or arsenical poisoning had never been known, and the employer would have had a perfect defense in an action for the death on the ground of its failure to obey the statute relating to occupational diseases; but there was no evidence tending in any degree to prove that the arsenical poisoning of the deceased was a disease incident to the occupation. The award was therefore upheld.—Matthiessen & Hegeler Zinc Co. v. Industrial Board, (Ill.) 120 N. E. 249.

Privileged Communications.—The Utah Supreme Court holds that a plaintiff in an action for personal injuries, who testified as to a physician's treatment of and statements to him as to the nature of his injuries waived the physician's privilege under the Utah statute. The erroneous exclusion of the testimony of the attending physician (his privilege having been waived), offered by the defendant as to his treatment of and statements to the plaintiff, was held prejudicial error.—Dahlquist v. Denver & Rio Grande R. Co., Utah Supreme Court, 174 Pac., 833.

Military Medicine.

Flavine and B. I. P. P. in War Surgery.—There has been a good deal of discussion with regard to the antiseptic and healing merits of proflavine, acriflavine and brilliant green as demonstrated in the treatment of wounds incurred in war. Some have eulogized them highly while others have stated that they have shown themselves of little or no use. It is beyond the scope of these remarks to deal with the controversial points which have arisen with respect to flavine in particular. It will suffice to say that in the hands of Professor Browning of the Bland Sutton Institute, London, the use of flavine has met with conspicuous success, and that many surgeons in the base hospitals in France, England and the East have testified to value of flavine in the treatment of wounds.

Captain N. Reader of the Dehra Duu Hospital, India, for Indian troops, writes in the *Indian Medical Gazette*, November, 1918, on war surgery among Indian soldiers. The hospital is intended entirely for Gurkha patients, but occasionally a Mohammedan is admitted for special treatment. During the past two years, most of the cases have come from Mesopotamia, but France, Gallipoli, Waziristan and Palestine have all contributed a share. The Dehra Duu Indian War Hospital is the last medical unit in the line of evacuation for Gurkhas. As a result of this, the cases that arrive for treatment are generally of a very chronic nature, and not such as respond easily to treatment. The highly infected, grossly suppurating wounds that fill the wards of the more advanced base hospitals are relatively few. In their place are found chronic sinuses, malunited fractures, ankylozed joints, deep seated foreign bodies, old nerve injuries, and the like. With reference to flavine Reader says that in his experience and in that of his colleagues flavine has proved of great clinical value, and they consider that it occupies a high place in the armamentarium of the surgeon. Its greatest field of usefulness is in severely septic wounds. They have found that the temperature becomes quickly reduced, signs of inflammation around the wound rapidly subside and the patient feels much improved in general well being. After a few days, a thick yellow, fibrinous membrane begins to form, and the continuation of flavine after this point probably does more harm than good. The membrane is readily dissolved away by lysol, leaving underneath a healthy granulating surface. The simplicity of technique in the application of flavine is a great point in its favor. For chronic wounds Reader and his colleagues are of the opinion that flavine is of no value. Reader is enthusiastic with regard to B. I. P. P., but is insistent that the paste must be composed according to Morison's original formula: iodoform 16 parts, bismuth sulphide 8 parts, and liquid paraffin 8 parts. The iodoform and bismuth should be thoroughly mixed in a mortar and the paraffin added gradually. When the paste has assumed the required consistency, it should be taken bit by bit and rubbed down on a slab with a spatula. It is most essential that no grittiness should be present and the whole paste should be perfectly homogeneous. Failure to prepare the paste properly will cause disappointment in results. Exact attention to detail is the key of success.

At Dehra Duu it was found that bismuth paste was by far the most useful substance in the treatment of the majority of wound cases, both in the operation theater and in the ward. For injecting the paste into sinuses a urethral syringe serves the purpose admirably. The plunger is withdrawn, and the syringe partially filled with the paste at the wide end. On returning the plunger the paste may be expressed as a fine ribbon from the nozzle. The nozzle of the syringe is boiled after each injection. It is not wise to boil the whole syringe, as the paste goes black. The black paste in the nozzle should be expressed before the next injection.

The American Army Hospital in France.—The Army Medical Corps, when confronted with the problem of choosing a hospital center in France, selected Beaume, in the Côte-d'Or region, where in the course of a few months one of the largest hospitals in all France has sprung up. This institution covers a square mile of territory, has 600 buildings of a permanent type, with accommodations for 25,000 patients. It is more than fifteen times the size of Bellevue Hospital, the largest hospital in New York. The American Hospital is of such extent and magnitude that it is divided into 10 units, each capable of caring for more than 2,000 patients. Each staff consists of 30 officers of the Army Medical Corps, 96 nurses, and 200 enlisted men. The entire hospital is under the direction of Col. Clarence J. Manly of the Army Medical Corps, who has been in the service for more than twenty years. In addition to its own work the hospital staff during the month of December served the wooden barracks convalescent hospital near Beaume where about 17,000 patients were being cared for.

Germans Loot Ambulance Train.—According to a report from London, on January 10, an ambulance train belonging to the municipality of Frankfort, derailed just outside the Michaelstadt station, was stormed by practically the whole population of the town, which is about 5,000, and everything was cleared out of it, glasses, linen, tablecloths, sofas, couches, chairs, tables, and everything except structural fixtures, the train being left perfectly empty.

West Point Needs Hospital.—Hospital facilities at West Point were described as "pitifully inadequate" by Colonel W. H. Haskins, at a hearing by the House Military Committee on the Military Academy appropriation. Colonel Haskins recommended that $465,000 be appropriated for a new hospital.

Refuses to Release Physicians.—The request made recently of the War Department by the Springfield, Mass., Board of Health for the release of several local physicians from service in the Medical Corps of the Army to aid in the local influenza situation has been refused. The information is given that the release of medical men from army service is under general orders of the War Department, and therefore out of control of the Surgeon-General. With the exception of a limited number of cases there will be no discharges save at places where the men have been serving.

MEDICAL RECORD.

New York, January 18, 1919.

A STUDY OF AMEBIC DYSENTERY.

THE war, so far as medicine is concerned, has had two conspicuous results. It has afforded unique opportunities for the close study of various diseases, of some of which the etiology is obscure, and treatment both preventive and remedial more or less empirical. Undoubtedly, these opportunities have been and will be seized so that many diseases, especially those occurring chiefly in the tropics, will in the future be largely prevented and methods of treating the same will be considerably improved. On the other hand, it has had the effect of conveying diseases practically all over the world. Maladies indigenous to certain climates or localities have been imported into places in which they were almost unknown before, owing to the extensive movement of troops. Tropical diseases which have been restricted to certain parts of the tropics have been thus conveyed to other portions of the tropical zone and have even been brought into temperate climates.

Lieutenant-Colonel John M. Cowan and Captain Hugh Miller, R. A. M. C., writing on dysentery in the *Journal of the Royal Army Medical Corps* for September, 1918, draws attention to these facts, and quotes Colonel Sandwith as saying that it had been anticipated that the dysentery in Alexandria in the autumn would be chiefly protozoal, whereas it had been mainly bacterial. Captain Lumb is quoted as stating that while the dysentery in East Africa prior to the war was wholly amebic, the bacillary affection had been frequently seen there since the arrival of the Indian troops in the autumn of 1914. On the other hand, cases of amebic dysentery have occurred in England in men who had never been away from home.

The authors, therefore, lay particular stress on the point that accurate diagnosis of the cause of dysentery in each individual is essential in order to ensure successful treatment. As is pointed out, the diagnosis of amebic dysentery is beset with many difficulties, and a really accurate diagnosis can be made only by microscopic examination of the stools. A single negative examination is of little value. In the author's cases the parasite was found only at the first examination in 60 per cent. The stools must be fresh and clean, for cold and prolonged exposure to the atmosphere rapidly destroy the amebas, a result which also follows the admixture of stools and urine, and treatment by emetine. A laxative should be administered in every case and the mucus, exudate, and sloughs of the mucous membrane examined. In cases where microscopic examination is impossible, and in fact in every case, due attention should be paid to the other data. The probable source of the infection and the nature of the dysentery prevalent are especially important. Moreover, recurring attacks of dysentery, chronic dysentery, dysentery which fails to react to general treatment, and dysentery associated with enlargement of the liver, hepatitis, and perihepatitis, are most generally amebic in origin.

Cowan and Miller state that the treatment of amebiasis of the intestines consists in the administration of ipecacuanha or emetine in sufficient doses over a sufficient length of time, and owing to the discomforts attending the administration of large doses of ipecac by the mouth emetine is almost always given hypodermically. It is still necessary to emphasize the fact that a short course of treatment will not cure amebic dysentery; a prolonged course is required, and should be continued even after dysenteric symptoms have completely disappeared. Regarding the administration of ipecac, the authors have found that it rarely occasions sickness if given with thirty grains of bismuth carbonate and five grains of sodium bicarbonate about 9 o'clock at night and three hours after the last meal. It should be mentioned that in certain cases in which the dysenteric symptoms persist after emetine has been injected for some time it is the custom of the authors to follow up the hypodermic course by a course of ipecac given by the mouth in five or ten-grain doses for two weeks.

The main point to be borne in mind in order to derive good results from the treatment of dysentery is first and foremost to make sure by careful diagnosis the form of dysentery. When it has been established to be amebic, a cure will not be obtained unless the treatment is prolonged.

MALIGNANT DISEASE ARISING IN THE SEBACEOUS GLANDS OF THE PENIS.

CANCER of the sebaceous glands of the penis offers special characteristics which always indicate its starting point, which is on the glans or mucosa of the prepuce. All causes favoring stagnation of sebum eliminated by the glands in the balanopreputial sulcus greatly aid in its development. The lesion begins as a verruca with a scaly surface and oval contours and rapidly increases in size so that within a year or even less the neoplasm offers formidable proportions. As soon as the indurated nucleus develops between the glans and prepuce, the latter is infiltrated throughout and assumes the consistancy of pasteboard. Even when a congenital phimosis does not exist, shortly after the evolution of the epithelioma has got under way, a cancerous

phimosis will develop, the result of the inflammation which invariably accompanies warty growths and which also hastens the evolution of the malignant process as a result of the accumulation of sebaceous products.

If the patient has a congenital phimosis a direct examination of the lesion may be impossible, but almost from its very beginning it gives rise to the symptoms of a balanoposthitis with a sanious discharge, and soon the penis increases in size, offering the characteristic, one might almost say pathognomonic, shape of a club or a clapper. When the neoplasm appears outside the foreskin, having overcome the resistance offered by the phimosis, it at first assumes the form of a reddish, ulcerated verrucous mass. Soon afterwards, bosses develop over it and in turn become eroded, giving vent to a foul-smelling discharge. These bosses continue to enlarge, their surface continues to erode, and soon they are transformed into true vegetations with a broad base which extends in depth and surface. The surrounding skin is tumefied, red, and thicker than normal, and also presents irregular projections which become purple in color as they are nearer the ulcer.

Although the growth may finally almost surround the penis like a ring, the glans is always respected. When the neoplasm has attained an enormous size and the entire organ is involved in the process, a compression of the urethra of a purely mechanical nature takes place, causing difficult micturition. There is no invasion of the urethral mucosa, although this may occur after the corpora cavernosa have become infiltrated by the neoplasm, but this occurs only at a very late date in the process.

The inguinal lymph-nodes are usually invaded by the tumor cells, but this is a slow process and takes place only late in the evolution of the growth, although in some instances offering a more malignant character they may be involved earlier. These malignant cases are those where the perturbation of the cell elements more closely resembles the embryonal state and where the sebum, being younger, is consequently more nefarious. These cases are less common and are prone to recurrence in the lymph-nodes after a radical operation has been done.

A rather distinctive character of sebaceous epithelioma of the penis is its usually slow evolution. An ordinary cancer undergoes its evolution more quickly and presents a truly malignant aspect, soon ending in cachexia. In the sebaceous type the general health remains good and it is only after the lapse of a number of months that there is a decline in the health. The organism seems to accommodate itself much better in the cases under consideration because the morbid process is in fact a sebaceous degeneration and the keratinised products are far less toxic. Nevertheless, there are cases running a very malignant course, and this eventuality must never be lost sight of in making the prognosis.

ARTIFICIAL ABORTION IN ANTIQUITY.

THIS subject has recently been considered *in extenso* in a Paris graduation thesis. It seems that up to a certain period of antiquity this act was not interdicted. The code of Hammurabi, the Mosaic Law, did not condemn it. In the later Judaic law the fetus was not regarded as an independent existence but merely as part of the mother. In Egyptian lore one seeks in vain for prohibition of abortion. But in the Vedas, Avesta, and the laws of Manu abortion is condemned in or out of wedlock. The crime was against the Deity but not against society.

In Greece, from early times, abortion was common, and the thinkers of the time justified it. Birth control was deemed an inherent right. Infanticide was legal in Sparta. In Athens, with its culture, there was a critical pose. If a father wanted children and the mother defeated this desire by committing abortion on herself a question was indeed raised, but no prohibition and no penalties are in evidence. The act of abortion was done by the midwife of the period, who was the obstetrician and gynecologist *ex officio* of the day. Medicines by the mouth and pessaries were the usual resources for artificial abortion. The grave prognosis of abortion was known to Hippocrates.

Under the Cæsars the Roman satirists deplored the frequency of artificial abortion, and Juvenal observed that wealthy women no longer bore children. The Romans of the day held to the old belief that the fetus had no rights—was only part of its mother. The leading motives for abortion were to conceal illicit relations and to preserve female beauty—for "women aged quickly in Rome." In their dilemma the Roman women turned to all kinds of "wise women" besides midwives—fortune-tellers, sorceresses, perfumers, and what not. The enfranchised Greek ex-slave was especially in demand. There is evidence that septic abortion of fatal termination was common. The first evidence of penalty was the exile of the guilty mother for a time in the view that her status was that of an alien and not a citizen. Abortionists were punished only when the mother died. The doom of abortion came with the ascendancy of the Christian Church, which urged the doctrine of the rights of the unborn child as a separate creature.

FUTURE OF ARMY LABORATORIES.

IN the bulletin of *Le Progrès Médical* for December 5, Helme discusses this subject in as far as it affects France. The war created a great demand for scientific men and the latter had to requisition a great deal of apparatus and material. Laboratories were established wherever there were troops. It is doubtful whether Claude Bernard or Pasteur himself had such an installation. The war made abundant opportunities for experimentation. Instruments of precision to aid the deceptive senses have multiplied. Perhaps France will be a Mecca after the war for students from other lands. The French have originated, but the German, their enemy, has profited materially. To select one ex-

ample out of a thousand, the French showed the feasibility of utilizing the nitrogen of the air, but the Germans turned this knowledge to advantage, and especially in offsetting the effects of the blockade. In France it was Tellier who, poor and alone and without apparatus, but highly ingenious, extracted nitrogen from the air and made from it ammonia long before the Germans had learned the trick. Had Father Tellier had governmental or other support he would have made enough ammonia for home consumption and would have enriched France through the supply of fertilizer. If these laboratories are not to perish they must be endowed and made centers not only of practice but of teaching. In the same connection the author raises the query as to what is to be the fate of *x*-ray plants and surgical apparatus. The answer is not difficult, for many civilian laboratories are wretchedly in need, especially physiological laboratories. Other apparatus released is concerned with fumigation and sterilization. Much apparatus can be used for the teaching of physics—chronographs, oscillographs, etc. The proper disposition and utilization of these properties will no doubt have a very considerable bearing on the scientific future of France.

Figueira's Syndrome.

At a recent session of the Medical Society of the Bahia Hospitals it was proposed to give the name of a new syndrome to its discoverer, who is a well known Brazilian pediatrist (*Brazil-Medico*, July 6). This syndrome is believed to be an attenuated, sporadic type of acute poliomyelitis. The affection is evidently of rare occurrence, which makes it difficult to study, and moreover is benign, so that its clinical significance is not great. There appears to be only a temporary hyperemia in place of organic lesion of the nerve centers. A case cited in a child of 20 months presented as chief symptoms weakness of the neck musculature, so that the head could not be held erect. There was also slight spasticity of the muscles of the lower extremities and exaggeration of the tendon reflexes. There was a lively Babinski reflex. The infant had been born at term but there were evidences of retarded cerebral development, and the case was judged not to be one of Figueira's syndrome. In another case regarded as a true example of the latter the diagnosis might well have been postdiphtheritic paralysis because the patient had recently suffered an attack of diphtheritic angina. But the only muscles to suffer were those of the neck, paralysis being absolute and of the flaccid type. There were no other symptoms of any kind, and the paralysis had disappeared completely in 15 days. This affection does not agree with any known case of diphtheritic paralysis and is typical of the syndrome already placed on record by Figueira. In the discussion which followed the reading of the paper one member expressed the opinion that the case narrated was one of diphtheritic paralysis, but if it was it was certainly unusual, for the symptoms presented differed greatly from those of a typical case of this condition. Fernandes Figueira is director of the Policlinic for Children in Rio de Janeiro.

News of the Week.

New Health Insurance Measure.—A Health Insurance Bill was introduced into the Lower House of the New York State Senate on January 8 by Assemblyman Joseph Steinberg. The purpose of the bill, which aims to supplement the inadequacies of the Workmen's Compensation law, is "To conserve human resources of the State by establishing for employees and dependent members of their families a system of mutual health insurance funds under the supervision of the Industrial Commission." The bill provides that beginning with the fourth day of disability on account of illness or accident a weekly cash benefit, equal to two-thirds of the insured person's earnings, provided that the cash benefit shall not be more than $8 a week, or less than $5 a week, except that if the insured person's earnings are less than $5 a week cash illness shall equal his full weekly earnings. The bill provides a cash illness benefit to dependents. Medical, surgical, dental, and nursing attendance and hospital treatment, as well as funeral expenses, are provided for. The costs of the insurance is to be borne one-half by the employer and one-half by the employee. Where the weekly earnings of the employee are less than $9 but more than $5 contributions are to be borne three-quarters by the employer and one-quarter by the employee. Where the weekly wage of the employee is less than $5 the contribution is to be borne entirely by the employer. The bill also carries a maternity insurance and provides for instruction in disease prevention, appropriation for this purpose to be made with the consent of the Industrial Commission.

Bill to Block Health Insurance.—The first bill for 1919 to be introduced into the New York State Senate was a bill calling for the reorganization of the Department of Health and including an appropriation of $2,250,000. This measure was introduced by Senator Ross Graves of Buffalo at the request of the Associated Manufacturers and Merchants of the State. The bill had its inception in an investigation of compulsory health insurance. The sponsors of the bill say it is designed as a sickness prevention bill. They expect that the bill will meet with considerable opposition, but regard it as a start in the right direction.

Politics Charged in New York Health Department.—Mayor Hylan is again accused of renewing his attempts to throw the New York Health Department into politics. The Central Federated Union, at a meeting on January 9, adopted resolutions protesting against what it termed the "secret and surreptitious" removal by Health Commissioner Copeland of Louis I. Harris, who has been director of the Division of Industrial Hygiene, from that position and placing the division in his own office. The Central Federated Union in these resolutions complains against the disturbance of the work of the Division of Industrial Hygiene, as constituting a danger, not only to workers in industry, but to the community as a whole, and asks that a committee of five be appointed to take such action as may be necessary, jointly with other central bodies, to exert every effort to prevent this unfortunate interference

with an official who has won the confidence and respect of all those interested in health protection of the public. In replying to this charge Dr. Copeland declares that no powers will be taken from Dr. Harris, but that he felt that the work of the Division of Industrial Hygiene was so important that he desired to have it directly under his supervision. Commissioner Copeland further states that Mayor Hylan has had nothing to do with the change and did not know of the existence of the Division of Industrial Hygiene.

Program of the Rockefeller Foundation.—The Rockefeller Foundation has just announced its plans for extensive work in public health and medical education for the year 1919. The estimated income of the fund for 1919 is $6,750,000, and against this the budget provides for $2,264,130 for public health and $3,662,504 for medical education. The other items of the budget are $103,000 for miscellaneous payments on long term appropriations and $146,662 for administration. The amount still available for appropriations is $465,110. The public health activities to be carried out during the year will consist chiefly of efforts against yellow fever, tuberculosis in France, malaria and the hookworm disease. The Yellow Fever Commission, headed by General William C. Gorgas, is starting a war on the disease which it is hoped will result in its complete elimination. The Commission on Tuberculosis in France, which during the war has been co-operating with the American Red Cross, will continue its work on an enlarged budget at the request of the French authorities. Demonstrations in the control of malaria will be carried on in two southern states. The campaign against the hookworm disease will be waged during the present year in twelve states of America and twenty-one foreign states and countries. In addition to this public health work to be carried out by the Foundation's International Health Board, appropriations have been made for special studies and demonstrations in mental hygiene by the National Committee for Mental Hygiene, for the creation and maintenance of a School of Hygiene and Public Health at Johns Hopkins University, and for the development of public health nursing. The chief work of the Foundation in medical education will be in connection with the development of modern scientific medicine in China through the Foundation's China Medical Board. Other expenditures for medical education are for special work of the Rockefeller Institute for Medical Research and toward a contribution for the development of the medical school of the University of Chicago. The following will be its war work activities: Continued maintenance, at the request of the War Department, of the War Demonstration Hospital. Work of Medical Division of National Research Council, which was appointed by the President to coordinate the scientific resources of the nation. Assistance in care and treatment of soldiers mentally and nervously disabled. Payments on pledges made in 1918 to United War Work Fund and to work under the direction of the Commissions on Training Camp Activities.

Typhus Spreads in Russia.—According to advices received at the State Department in Washington, on January 4, typhus fever is spreading in Russia, there being 260 cases reported from Ekaterinburg, 700 at Chilbinsk, and 200 deaths from the disease at Tomsk during December. Irkutsk reports 450 cases. The disease is prevalent among the civilian as well as the military population and is also prevalent in the Bolshevik prison camps and to some extent in Austro-German camps. A Miss McBride, an American Red Cross nurse, is reported to have died from the disease in Tumen recently.

Want and Disease Reduce Population of Poland. In making an appeal for medicines, food, and fuel, Dr. Chodzko, Minister of Public Health of Poland, says that there were at Lodz, in 1913, 12,000 births and 17,000 deaths. At the present time the annual rate is 2,000 births and 8,000 deaths. Tuberculosis he finds is four times as menacing as other diseases, since the Germans refused to give patients medicines, and confiscated the food and fuel resources. The country is in great need of quinine, morphine, camphor, vaseline, oils, cotton, wool, and gauzes.

Increase in 1918 Death Rate Due to Influenza.—The Census Bureau at Washington reports that the recent epidemic of influenza caused 111,588 deaths in the forty-six largest cities of the United States and increased the combined death rate of those communities, in 1918, to 19.6 per thousand, the highest rate recorded since 1880, when the death rate was 19.8 per thousand. All told the deaths for the year in these forty-six cities numbered 442,374. The death rate in some of these cities is as follows: Baltimore, 26.8; Nashville, 26.4; Pittsburgh, 26.4; Philadelphia, 24.2; Washington, 23.6; Boston, 22.0; Buffalo, 21.2; Cincinnati, 20.6; San Francisco, 20.5; Newark, 19.5; New York, 18.8; St. Louis, 17.6; Chicago, 17.1; Los Angeles, 16.4; Cleveland, 16.0; Milwaukee, 14.4; Grand Rapids, 14.0; St. Paul, 13.9. New York's mortality rate is the highest it has had in fourteen years and is in marked contrast to that of 1917, when it was 15.2.

Supreme Court to Define Drug Law.—The Department of Justice has filed briefs in the Supreme Court in two cases under the Harrison antinarcotic law in which the constitutionality of the license and punitive taxing powers of Congress were assailed. The particular provisions attacked are those prohibiting the sale of the drugs except on official order forms or on physicians' prescriptions given in good faith to patients. It is the Government's contention that the right of Congress to pass excise on punitive taxes is clearly established by the tariff acts and other similar laws.

Brookline Doctors Raise Fees.—The Brookline Medical Club has voted to increase the fees of its members for house and office visits at least one dollar above the previous charge. The fee for a visit between 10 P. M. and 8 A. M. is increased to from $5 to $15. For a visit between 7 P. M. and 10 P. M. the fee is now $4 to $6. A visit in consultation is from $10 to $25 instead of $10 to $20. Instead of a "suitable charge" for advice by telephone the fee for such service is definitely from $1 to $2. For advice by letter a fee of from $2 to $15 may be charged.

Essex County, N. J., Tuberculosis Hospitals.—Essex County, which now maintains two hospitals for the care of tuberculous patients, one at Soho with about 200 beds and one at Verona with 85, is constructing a new hospital which will afford accommodations for 100 or 150 more patients. The tuberculosis agencies of Essex County find that the care of discharged soldiers is giving them additional work. Dr. H. B. Dunham, for the past ten years assistant superintendent of the New Jersey State Sanatorium for Tuberculous Diseases at Glen Gardner, has been selected superintendent of these hospitals.

New Brooklyn Hospital Opened.—The Carson Memorial Hospital, at Crown Street and Albany Avenue, Brooklyn, which was donated to the city by the family of Carson C. Peck, was formerly opened on January 10. The Rev. S. Parkes Cadman accepted the gift in behalf of the city.

Beth Israel Hospital Acquires Property.—Beth Israel Hospital has completed the assembling of the site for its new building in Stuyvesant Square through the purchase of two dwellings at the northeast corner of Livingston Place and Sixteenth Street. The combined plot now under the ownership of the hospital consists of 189.7 feet in Livingston Place and 129 feet in both Sixteenth and Seventeenth streets. A sixteen-story main hospital building has been planned for the site to which will be added the seven-story Stuyvesant apartment house which has been remodeled as a part of the hospital at a cost of $85,000.

Course in Occupational Therapy.—A course in occupational therapy for women who wish to train themselves for aid in the re-education of wounded soldiers is offered by the Central Branch of the Young Women's Christian Association, 610 Lexington Ave., New York City. A course is also being offered for women who wish to be trained to relieve nurses' aids in hospital work.

Theater for War Hospital.—Debarkation Hospital No. 5 in the Grand Central Palace, New York is to have a theater of its own, built, equipped and maintained by the Stage Women's War Relief. A considerable sum of money for this purpose is already in hand.

Gifts and Bequests.—Bequests of $10,000 each to Mount Sinai Hospital and the Mount Sinai Training School for Nurses, New York, are provided for in the will of Kalman Haas.

A gift of $10,000 for a children's ward in the Holyoke City Hospital has been made recently by John P. Bagg.

The United Hospital Fund of the New York non-municipal hospitals has received thus far this year $32,080.

Through an anonymous donor the Long Island College Hospital has had placed at its disposal a farm for keeping animals used in research. Experimental work has already been begun on fowl influenza, diphtheria and chickenpox.

Lieut.-Col. George H. Burr has been appointed American Red Cross Commissioner for France, to succeed Harvey D. Gibson, who will remain in France as chairman of the Red Cross European commission.

Dr. Royal S. Copeland, Health Commissioner of New York City, has resigned from the new Milk Commission appointed by Governor Smith. He gives as his reason the possibility of facing embarrassment if called upon to exercise police control over his fellow members of the Milk Commission.

Medical Society Elections.—THE SOUTHERN SURGICAL ASSOCIATION, at its thirty-first annual meeting held in Baltimore, Dec. 18-20, 1918, the following officers were elected for the ensuing year: *President*, Dr. J. E. Thompson, Galveston, Texas; *Vice-Presidents*, Dr. Charles R. Robins, Richmond, Va., and Dr. George A. Hendon, Louisville, Ky.; *Secretary*, Dr. Hubert A. Royster, Raleigh, N. C. (reelected); *Treasurer*, Dr. Guy L. Hunner, Baltimore (reelected). New Orleans was selected as the next place of meeting.

THE AMERICAN CONGRESS OF INTERNAL MEDICINE, held in New York City, Dec. 30, 1918, elected the following officers for the ensuing year: *President*, Dr. Glentworth R. Butler, Brooklyn; *First Vice-President*, Dr. Frederick Fice, Chicago; *Second Vice-President*, Dr. Clement R. Jones, Pittsburgh; *Secretary-General*, Dr. Frank Smithies Chicago; *Associate-Secretary*, Dr. Joseph H. Byrne, New York City; *Treasurer*, Dr. Augustus Caillé, New York City.

THE PORTLAND (ME.) CITY AND COUNTY MEDICAL SOCIETY, at its annual meeting held in Portland, Dec. 18, 1918, the following officers were elected for the ensuing year: *President*, Dr. C. J. Smith; *Vice-President*, Dr. C. C. Moore; *Secretary*, Dr. A. J. Browning; *Treasurer*, Dr. Katherine Manion.

THE CLARK COUNTY MEDICAL SOCIETY, at its annual meeting held in Springfield, Ohio, Dec. 23, 1918, the following officers were elected for the ensuing year: *President*, Dr. D. W. Hogue; *First Vice-President*, Dr. Read L. Bell; *Second Vice-President*, Dr. Clarence H. Kay; *Secretary*, Dr. W. B. Quinn; *Treasurer*, Dr. Frank P. Anzinger; *Councillors*, Dr. C. C. Augustus and Dr. C. L. Minor.

THE BOSTON CHAPTER OF THE MASSACHUSETTS HOMEOPATHIC SOCIETY, at its annual meeting on Jan. 2, 1919, elected the following officers for the ensuing year: *President*, Dr. Wilson T. Phillips; *Vice-President*, Dr. Ernest M. Jordan; *Second Vice-President*, Dr. Albert W. Horr; *Secretary*, Dr. Clifford D. Harvey; *Treasurer*, Dr. Thomas M. Strong.

THE WEST VIRGINIA HOSPITAL ASSOCIATION, at its annual meeting held in Charleston, W. Va., Dec. 30, 1918, to Jan. 1, 1919, elected the following officers for the ensuing year: *President*, Dr. J. A. Guthrie, Guthrie Hospital, Huntington; *First Vice-President*, Dr. Charles F. Hicks, Emergency Hospital No. 1 Welch; *Second Vice-President*, Dr. S. B. Lawson, Logan; *Third Vice-President*, Miss Noel, Princeton; *Treasurer*, Miss Knight, Huntington; *Executive Committee*, Dr. J. A. Guthrie, Huntington; Dr. W. A. McMillan, Charleston; Dr. C. A. Wingerter, Wheeling; Dr. P. O. Clark, Wheeling.

THE YORK COUNTY (ME.) MEDICAL SOCIETY, at its ninety-fifth annual meeting held in Biddeford, Jan. 2, 1919, the following officers were elected for the ensuing year: *President*, Dr. A. S. Davis, Springvale; *Vice-President*, Dr. F. W. Smith, York Village; *Secretary*, Dr. A. L. Jones, Old Orchard; *Treasurer*, Dr. Charles F. Traynor, Biddeford.

THE NORWALK MEDICAL ASSOCIATION, at its an-

nual meeting, Jan. 2, 1919, elected the following officers for the ensuing year: *President*, Dr. A. H. Baldwin; *Vice-President*, Dr. H. C. Sherer; *Secretary-Treasurer*, Dr. James A. Meek.

The Talbot County (Md.) Medical Society, at its annual meeting, Dec. 31, 1918, elected the following officers for the ensuing year: *President*, Dr. Edward R. Trippe, Easton; *Vice-President*, Dr. James R. Merrit, Easton; *Secretary-Treasurer*, Dr. Joseph Ross, Trappe.

The Daughters of Hygeia, Auxiliary to the York County Medical Society, at its annual meeting in Biddeford, Me., Jan. 2, 1919, elected the following officers for the ensuing year: *President*, Mrs. C. F. Kendall, Biddeford; *Vice-President*, Mrs. F. W. Smith, York; *Treasurer*, Mrs. W. W. Smith; *Secretary*, Mrs. C. E. Thompson, Saco.

Obituary Notes.—Dr. Frank W. Jackson, a graduate of the College of Physicians and Surgeons, New York, in 1879, died at his home in New York City on January 8. He was a member of the New York Academy of Medicine and the New York Pathological Society, an alumnus of Bellevue and Roosevelt Hospitals, consulting physician to Bellevue Hospital and visiting physician to the Roosevelt Hospital.

Dr. Horace Melville Simmons of Baltimore and New York, a graduate of the University School of Medicine, in 1881, died suddenly at Mountain Lakes, N. J., on January 5, aged 65 years.

Dr. William B. Van Lennep, dean of the Hahnemann Medical College of Philadelphia, died on January 9 after an illness of two months. He was 65 years old and was a graduate of the Hahnemann Medical College of Pennsylvania in the class of 1880.

Dr. Chauncy M. Marstin, a graduate of the Rutland, Vt., Medical College, died suddenly at his home in Braintree, Mass., on January 6, aged 74 years. He served in the Civil War in the 142nd New York Infantry, and was present at Appomattox when General Lee surrendered. Dr. Marstin assisted in organizing the Braintree Board of Health, and was a member of it for many years.

Dr. Alvin Myers Struse, formerly of Philadelphia, died at Guatemala of influenza complicated by pneumonia on December 19, at the age of 29 years. He was graduated from Jefferson Medical College in the class of 1914 and he served as intern at the Episcopal Hospital of Philadelphia and the Abington Memorial Hospital.

Dr. Edward Humphrys died at Philadelphia on December 25 at the age of 61 years. He was graduated from Hahnemann and Medical College Hospital of Pennsylvania in the class of 1881.

Dr. Nathaniel H. Saxman died at Philadelphia on January 9 at the age of 53 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1890.

An Italian Camp University.—At the camp university of S. Giorgio there is given a course in pathological anatomy. In the first three months 200 autopsies were performed. Of interest is the frequency of sclerosis of the aorta in young subjects. Again in subjects dead of acute infectious diseases, persistent thymus is not uncommon. Another unexpected association was cerebrospinal meningitis with the anatomical lesions of tuberculosis.—*Pathologia.*

Correspondence.

CANCER DEATH RATE IN NEW YORK CITY DURING 1918.

To the Editor of the Medical Record:

Sir:—Mortality statistics are an interesting and instructive study in their relation to therapeusis, as all recognize. For if a new remedy or course of treatment for any disease were introduced and year by year the death rate from that disease was shown to rise, eager search would be made for other remedies or measures to check the same. Years ago tuberculosis was called the great white plague, increasing in mortality so greatly that fear was excited that it would sweep off nations; but we know now that with well directed medical care its death rate has diminished 30 per cent. since 1900 in the United States. Syphilis, the great black plague, swept through Europe and elsewhere in the sixteenth and seventeenth centuries, whole towns and communities being infected, often quite innocently, until the proper use of mercury with the recent introduction of salvarsan has largely rid the world of the fear of this foul disease. Leprosy was once alarming, but under wise management and the knowledge of its non-contagiousness it has lost much of its terrors. Yellow fever and cholera no longer threaten regions where scientific medical activity controls. But our recent experience with poliomyelitis and the Spanish grip shows that there is yet much for the medical profession to investigate and conquer.

Cancer, the great red plague, still holds its own as a menace to civilization, for the United States Mortality Tables show that since 1900 its death rate has risen nearly 30 per cent., almost as much as that of tuberculosis has fallen; and it is commonly asserted that 90 per cent. of those once affected die from the disease, under the prevailing treatment. It is certainly time to consider well what should be done to check this fearful mortality.

But the death rate from cancer in New York City, during the past year, 1918, seems to show that wiser counsels are beginning to prevail, as appears from the weekly reports of the New York Department of Health. During 1916, as previously reported, there were 4,635 deaths from cancer, malignant tumor (an average of 12.68 persons daily), while during 1917 there were 4,859 deaths, 2,143 males and 2,716 females (an average of 13.31 persons daily), an excess of 224, that is, an increase of almost 5 per cent.; whereas the increase in deaths from all causes was only 519, or less than 1 per cent.

During 1918 there were 4,895 deaths from cancer, 2,150 males and 2,745 females (an average of 13.39 persons daily), or an increase of only 36 deaths over last year; that is, less than 1 per cent., as against the 5 per cent. increase of 224 deaths for last year, 1917, over the preceding year.

If figures teach anything, they seem to show that in New York City the profession is beginning to learn that the heretofore rash attempt to cure cancer with the knife is giving way to wiser procedures.

OUR LONDON LETTER.

(From Our Own Correspondent.)

KING EDWARD'S HOSPITAL FUND FOR LONDON—MEDICAL MEN IN PARLIAMENT—RECRUITING FOR AVIATION—NEW PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

London, December 26, 1918.

A RECORD distribution of £200,000 has been made among the hospitals, consumption sanatoriums, and convalescent homes in the metropolitan area by King Edwards' Hospital Fund for London, the hospitals receiving no less a sum in annual grants for 1918 than £190,000 the balance of £10,000 being allocated to the other institutions. Several points are worth noting in this connection. The first and obvious one is that the public has appreciated the services of the hospitals during the fourth year of the war, as well as the difficulties entailed upon them by high prices and shortage of employees from honorary staff down to lift-boy. The addition to the subscriptions, contributed it should be pointed out by a public who was suffering as much as the hospitals from the price of living, is a testimony to the fact that the double rôle of the voluntary hospitals was recognized, namely that of ministering to the needs of the civil population, and that also of providing a large number of beds for wounded and sick sailors and soldiers, thus relieving the purely naval and military institutions. The second point to be noted is that the total of £200,000 given in one year is exactly double the total which was regarded, when the fund was started, as the ideal toward which the work should be directed, showing that day by day the charitable public is thinking in larger figures. The third point, which is a corollary of the second, is that while £160,000 of the total was applied in the form of grants to maintenance of hospitals, £30,000 was given as capital grants for reduction of liabilities, and in the main for schemes of improvement. This is a practical proof that those who manage the fund look forward to progression, and will forward anything bringing about this progression by reform of the existing pattern of metropolitan hospitals. One direction which this reform can take is obvious. A spot map of London shows at once that from the geographical as well as from the population point of view the sites of the institutions are capricious. The removal of Kings College Hospital to a place five miles southeast of its old home in the center of London has already taken place; the removal of Westminster Hospital is contemplated. This hospital at present facing the Abbey is separated by considerably less than a mile from Charing Cross Hospital and from St. Thomas' Hospital, while its activities also prevail over districts which can be catered for by St. George's Hospital, also distant barely a mile. This hospital, it is understood, is about to be removed also south of the river. Such great schemes of uprooting do not in their entirety, of course, fall into the hands of King Edward's Fund; they must be financed as a whole by the institutions concerned, possessing as they do funds, landed property, and valuable good-will. But all removals are expensive, and such domestic upheavals are considered by the Fund in the allocation of grants. But when a similar movement takes place among smaller, and usually special, hospitals, the assistance of the Fund will be valuable. It is obviously the policy of the Fund to promote schemes by which little special hospitals overlapping in object and sometimes situated in juxtaposition should be combined and even attached to big general hospitals as a special department of those hospitals. There is an immense saving in time of the staff and working of the administrators by any such judicious combination. To keep this sort of reform of hospital administration King Edward's Hospital Fund for London can be depended upon, and it is clearly going to be a policy of the future.

The results of the general election will not be largely determined until the last days of the year, but the counting has already taken place in several of the University Constituencies. Already two distinguished doctors can place M.P. after their names, Sir Robert Woods, who becomes a member for the University of Dublin, and Sir William Whittla, who will sit for the Queen's University of Belfast. At the election for the University of London Sir Wilmot Herringham was unable by the medical vote to detach the constituency from an old allegiance to Sir Philip Magnus, who was also the official candidate of this retiring government. Sir Wilmot Herringham was undoubtedly handicapped in his appeal to the electors by the fact that he is a graduate of Oxford and not of London, but as a physician on the staff of St. Bartholomew's Hospital, he is a recognized member of the University of London, within whose fold there are now included all the twelve great London schools of medicine. Moreover Sir Wilmot Herringham has been vice-chancellor of the University of London, the highest official post that is not purely honorary, so that those who abstained from voting for him because he got his degree on the shores of the Isis instead of on those of the Thames, were completely illogical.

Recruiting for aviation is a subject which has several times been discussed in these letters, because it is so keenly debated on this side. It is now accepted on all hands that a proper selection of men fit to fly can only be made by a properly selected body of medical men fit to test intending aviators. The day has gone by when it was assumed that athletic competency and a brave and lively heart turned any one between 18 and 28 into an accomplished aviator; but such wonderful achievements have been performed by a corps selected on no more scientific basis, that it must be assumed that the basis remains sound. It is the truth that competent physique and adventurous morale are essential characteristics of the successful aviator, but while it is the truth it is not the whole truth, and the lives of many of these heroic young men have been sacrificed while we were finding our way to some method of recruiting which went much further and far deeper. There can be no doubt that in the near future there will be organized by all progressive nations air services of public utility, the aerial post being the first one that will arrive. At once we see the

different kind of strain to which the civilian aviator will be subjected or compared with all flyers for touring or amusement purposes. To some extent he must abide by a time chart. In war the bomber could not wait entirely upon the weather. He was buoyed up by military duty to defy the atmosphere as well as the enemy's fire, and ascended in accordance with the needs of the fighting force; but war is a great emprise conducted on desperate planes, and no one could conceive subjecting the civilian employee to the appalling risks which the soldier must take. Civilization can go on if posts arrive a few hours late, but in the near past civilization was absolutely threatened unless certain men did certain appallingly dangerous things in accordance with a Colonel's stop watch. Still, the essence of the postal service is that it should be regular, and the civilian aviator in State employ will have to fly to some extent in defiance of meteorology, and he will require much delicate and intimate medical inspection before he is recruited. Let it be granted that a careful recruiting board would estimate general physique, the acuity of special senses, and the cardiac and pulmonary conditions in all candidates. There remains the fact that standards of aerial fitness will have to be arrived at which cannot be arrived at in ordinary recruiting methods. Capt. Ronald Carter, late a member of the Aviation Candidates Medical Board has published a test of the cardiorespiratory centers in the medulla which is a very good example of the kind of work that will have to be done in the medical examination of the aviation candidates of the future. He writes thus in the columns of *The Lancet*.

> The candidate is directed to expire so as to empty the chest and then to take a deep inspiration and blow through a tube so as to raise a column of mercury to the height of 40 mm. and keep it there for 40 or 50 seconds. The experiment may produce considerable embarassment, with marked flushing of the face, and when asked to describe his sensations the candidate will often say that he felt a "bursting in the head" or that he "felt giddy." This may be termed an abnormal answer. On the other hand, a youth who has good nervous control and a good cardiovascular system will hold his breath against 40 mm. Hg. pressure, with little or no discomfort for the same period, and his answer will be that he "wanted to breathe" or he "wanted more air." During the holding of the breath the pulse-rate in the two cases varies: in the normal boy the rate will increase from 20-30 beats per minute and stay there until the end of the experiment, while in the abnormal case the rate will increase to 60 or more beats per minute, and before the end of the experiment it will drop to a rate lower than at the commencement. I have watched the manometer test in a great variety of cases, and I feel sure that it has its value and should form part of our examination, because it affords evidence of the stability of the nerve centers which cannot be elicited in any other way; but, of course, it should never take the place of a thorough physical examination.

Some statistics on this subject have already been published, but Captain Carter admits that more work will be required before the test can be generally accepted. Every one, however, will agree with his proposition that at this early stage in the problems of flight we must have open minds with regard to the tests for flying men. And we must remember also that the test of to-day will not necessarily be the test of to-morrow, because the whole science and art of aviation is still in its babyhood. It used to be thought wonderful for an aeroplane to travel a mile in a minute. To-day this is often not more than half the speed. An altitude of 10,000 feet may be as much as will ever be required for practical purposes, but if that altitude is reached, at these terrific speeds the aid of the highest kind of physiology is postulated to help in the decision how the body can be best prepared for such sudden changes in pressure and temperature.

Sir Robert William Philip has been elected president of the Royal College of Physicians of Edinburgh, at the expiration of the term of office of Dr. William Russell. Sir Robert Philip, who is lecturer and examiner in chemical medicine to the University of Edinburgh, as well as Senior Physician to the Royal Infirmary in that city has pursued very extensively the measure for the prevention of tuberculosis, and to some extent has been a pioneer in this branch of therapeutics. He founded in 1887 the first tuberculosis dispensary and was largely responsible for the foundation of the Victoria Hospital for Consumption, near Edinburgh, with its associated farm colony. Much of the national system for the prevention, control, or cure of tuberculosis has followed lines indicated in Sir Robert Philip's teaching.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

NO ABATEMENT IN THE PREVAILING EPIDEMIC—THE 1,500TH Y. M. C. A. HUT—HELPING THE WAR ORPHAN FUND—AMERICAN SOLDIERS AT THE FRONT STILL FIGHTING—QUARTERS FOR THE AMERICAN PEACE MISSION.

PARIS, December 9, 1918.

VITAL statistics published by the Paris municipal authorities for the forty-third week of the year, show a considerable increase in the number of deaths that occurred in the capital during that period as a result of the epidemic of grippe that is now raging. The deaths total 2,566 as against 1,944 during the previous week, while the average for the season as shown by medical records is 721.

In the city of Paris the total number of deaths recorded last week was the largest received since the beginning of the epidemic, although the number of cases entering the various hospitals remained more or less stationary. On the other hand, figures for the beginning of this week show a decline. M. Autrand, the Prefect of the Seine, yesterday sent to the fiftieth commission of the Municipal Council information which tends to show that the epidemic has abated during the last forty-eight hours. Reports on the condition of the epidemic outside of Paris and the various departments of the country vary, some showing an increase and others a decrease in the number of cases. In Toulon Vice-Admiral Lacaze has ordained that in all churches, chapels, temples, etc., a thorough disinfection be made. Hotel proprietors, restaurant keepers and bar owners are instructed to clean thoroughly their establishments with antiseptic substances. As a result of the large number of deaths recorded in Grenoble by reason of the grippe epidemic, and

the apparent lack of necessary precautions against the same, the Departmental Council of Hygiene has decided to hold an inquest. The closing of all public halls, theaters and places of amusement has been ordered until further notice. The mayor of Toulouse has suspended all funeral processions and ordered that the bodies be transported directly to the cemeteries, where friends and relatives of the deceased may meet for the burial services. Although the epidemic at Annecy has shown a tendency to decrease, nevertheless the severity of the precautionary measures, ordering a daily disinfection of all public places, has not slackened to any degree.

Grippe is by no means a new disease. Dr. Gaullieur L'Hardy calls attention in the *Liberté* to an article by Professor Robert Odier in the *Journal de Genève* recalling the terrible epidemic of 1795, which affected more than 50,000 people in the city of Liverpool alone. It did not disappear until after the application by Louis Odier of the principle discovered by the learned French chemist, Guyon de Morvan—the exposure to nitrous acid fumes. Thereafter the discovery was used with astonishing success in hospitals, prisons and on board ships. The inventor of this method of disinfection, in order to obtain the salutary vapors, simply poured sulphuric acid on sea salt. Dr. Odier goes on to say that, "in laboratories and factories, where the workers are constantly exposed to vapors of nitric, nitrous and hydrochloric acids, there was not a single case of grippe." He states that, following numerous observations and tests, rooms and halls could be fumigated without any inconvenience whatsoever to the inhabitants, and, furthermore, that it left the air, garments and surroundings in a perfect state of cleanliness, and that one might approach the patients without the slightest risk of infection.

Mr. Henry P. Davison, chairman of the War Council of the American Red Cross, was received yesterday afternoon at the Hotel de Ville by the Paris Municipal Council. Most of the American members of the American Red Cross organization in Paris were present at the ceremony. Marshal Joffre was among the guests. The French Government was represented by Mr. Mourier, Under-Secretary of State. Speeches expressing the gratitude of France for the splendid work done by the Red Cross in France were made by M. Chassaigne-Guyon, M. Autrand, Prefect of the Seine, and by the Prefect of Police. Mr. Davison replied by outlining the work accomplished by the American Red Cross.

The American Committee for Devastated France, which has been closely affiliated with the French Government and the French military authorities, yesterday established a canteen near Laon to take care of French prisoners returning from Germany. This was done at the request of French headquarters. The call came on Monday, and immediately the American Committee rushed off supplies from Paris in its camions. This is the third time that the American Committee has gone to the relief of the French soldier. In March and June its workers fed many thousands of soldiers, when the Allied armies were falling back, giving hot meals, from rolling kitchens, to soldiers who were exhausted from fighting and lack of food. The American Committee's chief work has been with the French civilian population in the districts from which the Germans were forced to withdraw. After the French and Americans pushed forward from Chateau-Thierry, and the civilians had returned to the villages of that district, which were almost entirely destroyed, the American Committee took up the task of supplying and distributing food to the people, who were practically destitute. The American Committee has been carrying on its relief work in France since 1916. The French Government assigned as the territory for its rehabilitation work the cantons of Coucy-le-Chateau, Vic sur Aisne and Soissons, without the city itself.

The American Fund for the French Wounded is continuing its work as if the armistice had never been heard of. There has been no let-up in the hospital work—in fact, the winter program will show a constant increase in the help given in all directions. The Christmas bags are arriving and every wounded soldier in the hospitals supplied by the A. F. F. W. will receive his bag and other gifts. The motor service of the American Fund for French Service has become a French military section under the Service des Automobiles aux Armées. This means that the autos are now run with French military numbers and enjoy greater liberty of movement than heretofore. The central garage of the A. F. F. W. is in Paris, but a group of automobiles is also stationed in Lorraine. The rest of the service throughout France depends upon the General Headquarters of the regions in which it functions. The A. F. F. W. is sending out automobiles where needed. One was recently sent to Epinal to help the Baltimore and Minneapolis dispensaries. The fund is calling for muslin, flannel and gauze bands. Absorbent cotton and gauze are also in great demand.

6. The Surgeon and the Internist in the Treatment of Exophthalmic Goiter.—Israel Bram makes a plea for greater patience in the use of nonsurgical measures in the treatment of exophthalmic goiter, and suggests that in difficult cases the general practitioner, instead of turning the patient over to the surgeon, should consult with an internist experienced in thyroid therapy. He points out that: (1) Surgical indications in Graves' disease are: a. Marked pressure symptoms where dysphagia and dyspnea are distressing; dangerous pressure symptoms in exophthalmic goiter are rare and usually respond promptly to carefully administered nonsurgical measures. b. Malignant changes in the thyroid gland. c. Instances where a subject of nontoxic goiter suddenly finds herself afflicted with the

Basedowian syndrome. If it is concluded that the change is not due to the thyroid gland itself, but to the pressure of the tumor upon the cervical sympathetic, the removal of the latter or an operation upon the goiter to relieve the pressure may cure the patient. In this case, though the patient is suffering from what appears to be exophthalmic goiter, the case is not one of genuine Graves' disease, since there is no surcharging of the blood with thyroid substance. (2) All routes of research seem to lead to the conclusion that the modus operandi of the clinical picture of Graves' disease indicates a disturbance of many or all of the glandular tissues of the body; in such a status, operation upon the thyroid gland as a curative measure seems futile. (3) Some cases end in spontaneous recovery; it is such cases as these, where operation is performed, which are claimed as surgical successes. (4) The immediate and remote deleterious consequences of surgical interference, *e.g.* the accidental removal of the parathyroids resulting in tetany; the possibility of postoperative myxedema; injury to the recurrent laryngeal nerve directly through the operation or subsequently by pressure of scar tissue to paralysis of the vocal cords, all these "must give us pause." (5) Operation is further capable of harm by the devitalization of the patient through anesthesia and shock and the various other dangers because of the existence of glycosuria in many cases. (6) Surgical procedures dangerously postpone the utilization of successful nonsurgical procedures. (7) Proper nonsurgical measures, persisted in with patience and enthusiasm, will cure every early and moderately advanced case and more than seventy-five per cent. of advanced cases of Graves' disease. (8) All good surgeons seem to admit by word and pen that their success depends upon the careful nonsurgical postoperative treatment which they employ as the basis for permanent cure. (9) As the art and science of healing become less homogeneous and more heterogeneous in character, and concomitant with this change we find a comparative reduction in the number of general practitioners and an increase in the number of specialists; and since the innumerable number of men engaged in scientific research have added so much to our knowledge of the rôle of ductless glands in medicine, it seems fitting that men adopt the thyroid as their field of study and practice. In so doing, the thyroid specialist will not only find a broad and fascinating field of study, but he will also render humanity an inestimable service in helping to eradicate this disease which is becoming more and more a prominent factor, with the increasing strenuosity of modern life.

2. Origin of So-called Autointoxication Symptoms.—Walter C. Alvarez points out the fact that a diagnosis of autointoxication is frequently made when a physical examination would show other more definite causes for the symptoms, *e.g.* aortic regurgitation, chronic nephritis, myxedema, high blood pressure, tuberculosis, etc. The author believes that there is little evidence in favor of the views held by observers who find in intestinal stasis the cause of a long list of disease conditions, and that many of the assumptions on which they rest their case have been shown to be wrong. It is not sufficient to show that toxic substances can be formed during the bacterial destruction of nitrogenous matter; it must be demonstrated that these toxins are formed in the intestine, that they can pass through the mucous membrane, that they can escape destruction by the liver and reach the general circulation in amounts sufficient to produce symptoms, and that the symptoms produced by the repeated injection of small doses of these substances into animals are similar to those observed in constipated man. Moreover, the greatest care should be exercised in drawing conclusions from results of experiments *in vitro*, as it seems clear that in the bowel antibacterial forces are at work. It should also be remembered that nearly all the bacteria found in feces are dead, that organisms cannot multiply in constipated feces on account of the dryness and lack of nitrogenous food, and that the great number of intestinal bacteria produce no soluble toxins. Furthermore, absorption cannot take place unless the feces are liquid and churned actively to and fro, whereas the roentgen ray has shown that the feces begin to harden in the ascending colon and thereafter undergo no churning movements. The fact that the usual symptoms of the constipated disappear so promptly after a bowel movement proves that they cannot be due to absorbed toxins, and they must therefore be produced by distension and irritation of the colon. Such symptoms occur in nervous people, in whom the brain is profoundly influenced by afferent impulses from a distended, overactive and wrongly acting bowel. The author is of opinion that many symptoms of constipation are due simply to plugging of the lower end of the canal, which slows or stops the downward current and produces ripples of reverse peristalsis, which run up the bowel and break into deeper waves in the upper part of the stomach and esophagus. In this way, more than the usual amount of bile is carried back into the stomach and up into the mouth, leading to biliousness, lack of appetite, feeling of fullness after eating a few mouthfuls, coated tongue, etc. The relief experienced after taking calomel is due to restoration of the normal downward currents. Overwork, worry and lack of sleep may also give rise to symptoms attributed to autointoxication, and finally to constipation. In short, nervousness is generally the cause and not the result of constipation. The author points out that the old ideas of insidious poisoning led to the formation of hypochondriacs and he believes that the new explanation will help to cure many of them.

3. A Note on the Value of Germinated Beans in the Treatment of Scurvy, and Some Points in Prophylaxis. Major H. W. Wiltshire, D. S. O.
4. Beer and Scurvy. Some Notes from History. Alice Henderson Smith.

1. Observations on the Medical Examination of Aviation Candidates.—G. A. Sutherland indicates the necessity of adequate knowledge on the part of the medical examiner of the physical and mental qualities of the successful aviator. Attempts have been made to standardize "tests," but the fallaciousness of such methods in the past must be remembered and tests considered in the light of finger posts but not impassable barriers. As a result of his experience, the author suggests certain broad principles which may be taken as guiding standards in the examination of prospective aviators. From the medical standpoint, the following qualifications are necessary to meet the special dangers and duties of the air service—a good physique, a sound cardiovascular system, and a strong and stable nervous system. It should be remembered that it is the functional disabilities that swell the numbers of the "permanently unfit for further flying." It is essentially the physical fitness of the candidate that must be determined by the medical examiner, not the "flying temperament"; the mentality of the candidate must also be considered but this will be tested in the subsequent examinations that must be passed and unless there is actual mental defect or deficiency rejection is not indicated. The chief problem to be settled by the medical examiner is the determination of the functional and reserve powers of the vital organs of the candidate. A careful investigation into

the previous health and illnesses of the candidate is of paramount importance and particular inquiry should be made in regard to asthma, malaria, syphilis, rheumatic fever and chorea, digestive disturbances, migraine, petit mal, epilepsy, nervous debility, neurasthenia, shell shock, concussion with unconsciousness, chronic joint disease (especially of the knee), and diseases of active foreign service. Several of these form an absolute bar to service. A special examination should also be made of the eyes, nose, ear, and throat. It is to be hoped that the standard of normal binocular vision will soon be established. Mr. Arthur Cheatle has introduced various testing exercises which are useful not only as bearing on labyrinthine efficiency but as indications as to the nervous tone and stability generally. The internal organs must be examined to exclude organic disease and to test their functional activity, and particular attention must be paid to the cardiovascular and nervous systems. In considering the cardiovascular system, two separate abnormalities are recognized: organic disease and cardiovascular debility. As in the other services, the definitely disqualifying lesions are mitral stenosis and aortic regurgitation, the first being weighed according to the effect it has on the musculature and efficiency of the heart. A youthful type of cardiac irregularity which is not of any significance, is a quickening of the cardiac beat during inspiration and a slowing during expiration. The "missed beat" in itself is of no importance either, but if the candidate is conscious of it he is probably a potential neurasthenic. Any form of paroxysmal tachycardia, on the other hand, is a cause for rejection. If there is marked dilatation of the heart with persistently rapid rate, there is probably nervous myocardial disease or infection and the candidate should be rejected. Variations in the size of the heart are common and of no special importance; cardiac hypertrophy, however, usually associated with dilatation, is always pathological. Candidates exhibiting arterial thickening associated with renal disease, retinal or cardiac changes, or definite symptoms, should be rejected. A high systolic blood pressure is not a cause for rejection in the absence of organic disease. Cardiovascular debility may be said to have established itself as a clinical entity owing to the war. As yet there is no agreement as to the underlying causes of this condition, but from the clinical point of view the phenomena exhibited in civilian practice are: tendency to breathlessness, precordial pain and faintness, rapid thumping action of the heart, chronic tiredness, and defective circulation. In flying men who have broken down under instruction, the symptoms are: exhaustion, faintness, giddiness, blurring of vision, headache, palpitation, precordial pain, breathlessness, etc.; these probably are not so much the result of a flying career as the effect of strain on an individual already possessed of C. V. D. (cf. the condition known as D. A. H.). One of the difficulties met with in the examination of young candidates is to determine whether a rapid cardiac action is due to temporary excitement or is a permanent condition denoting nervous instability. The effect of calming words, rest, and exercise may settle this point, or the pulse may supply valuable assistance. As a rule, a slow pulse is a good sign. In some candidates the pulse volume may be good but the tension is badly sustained and in extreme cases of C. V. D., when the arm is elevated the pulse becomes almost imperceptible. In fact, the C. V. D. type seems to possess a circulation that is constantly "off duty" and unable to respond to any sudden change of conditions. Other signs are cold and cyanotic extremities, "white fingers," tendency to venous plethora which is probably associated with lack of tone of the abdominal muscles. The author describes certain tests which may be of value in the examination of such candidates. As a rule, however, the symptoms and physical signs of C. V. D. are accompanied by signs of debility in other tissues and organs, a common cause of rejection being a combination of cardiovascular and nervous debility. In considering the nervous system, it should be borne in mind that the candidate will be subjected to considerable strain in the flying service; and the matter of importance is not whether the individual is excitable or phlegmatic, but the amount of control he is possessed of. Exaggeration of the knee and elbow jerks and persistent dilatation of the pupils may be regarded as signs of nervous instability. The results of the balancing test are also of value. To sum up, therefore, a certain number of candidates are eliminated because of some definite medical or surgical disease, or of their previous medical history, or of other clearly disqualifying condition. Another group fall out, not from actual disease, but because the physique or cardiovascular system or nervous system is so much below par as to show clearly that failure in the flying service would certainly follow. While these two classes may not present great difficulty, the decision in the borderline cases is not so easy. Experience has shown, however, that a consideration of the physique, the cardiovascular system, and the nervous system will show that if one of these systems is functionally weak other signs of debility will also be found. Appropriate treatment, of course, should be ordered in case of remedial defects being noted. In other cases, development may not be complete on account of the age of the candidate and a final decision should then be reserved for six to twelve months. Decision as to the special branch of the flying service for which a candidate is best fitted should be reserved until training has been completed, and does not come within the province of the medical examiner.

December 14, 1918.

1. A Filtrable Virus as the Cause of the Early Stage of the Present Epidemic of Influenza. (A Preliminary Note.) Majors H. Graeme Gibson and F. B. Bowman and Captain J. J. Connor.
2. Medical Reports on Soldiers Discharged from the Army for the Conditions known as "D. A. H." and "V. D. H." Thomas Lewis.
3. The Common Factor in Disordered Action of Heart. Major L. M. Murray.
4. Intravenous Injections of Antimonium Tartaratum in Bilharziosis. J. B. Christopherson.
5. Fibroma of the Trachea. James B. Horgan.

3. The Common Factor in Disordered Action of the Heart.—Major L. M. Murray points out that the condition known as D. A. H. is always secondary. It may be the result of an hereditary taint, but usually the primary factor will be found to be some infection, accident or injury, or repeated mental shocks. Whereas such cases are usually accompanied by rapid pulse because the exciting factor has an affinity for and enhances the action of the cardiac sympathetic, the author cites the case of a patient with a comparatively slow pulse who had suffered from disordered action of the heart since boyhood. Major Murray suggests that the common factor of this condition is to be found in the body fluids. The role of the autonomic nervous system is that of the small child who starts the motor car and is unable to pull the levers of control. By means of its more or less continuous stimulation, a vicious circle begins: (1) stimulated autonomic system; (2) altered body fluids; (3) altered function—in which all systems, including the autonomic take a part. Similar changes take place in the acute infections and other diseases, and are followed by similar symptoms; their importance in the history of D. A. H. being that once the vicious circle has been created, it is entered upon again more readily. The relation of single or repeated mental shocks depends on the degree of shock and the stability of the autonomic nervous system. Breathlessness, especially on exertion, is the most common symptom of the condition and the author points out that under normal conditions the response of the respiratory center and muscles would be such that any potential alkalinity of the blood would be corrected. The alkaline balance of the circulating blood is disturbed quite apart from the respiratory system, and a further disturbance of this balance occurs as a result of deficient lung ventilation. The respiratory system in these cases cannot be judged by ordinary standards. The center bathed by abnormal fluids, with function either inefficient or exaggerated, is on a different plane. The respiratory muscles have every evidence of exhaustion. Since with increased hydrogen-ion concentration the avidity with which the blood gives up its oxygen is increased, clinically it would appear that both the center and the blood require to be further activitated by carbon dioxide in order to obtain the necessary response for ordinary effort. The author states that this explanation does not pretend to be more than an attempt to correlate the clinical appearance of respiratory action with certain changes in

the blood, and that it is brought forward with considerable trepidation but with the certain feeling that an analogy does not exist between the experimental injection of lactic or other acids and the autogenous disturbance of circulating fluids such as are present in these cases. Precordial pain, Major Murray believes, is merely the distress signal of an organ compelled to work in spite of a food supply, at least altered chemically. Starling has shown that the reserve power of the heart is enormous and is dependent almost entirely upon its nutrition. Palpitation, exhaustion, the vasomotor and other symptoms are explained by the changed character of the body fluids interfering with function. The author adds that this contribution must not be considered as more than clinical, based on observation and on deductions which he hopes are within reason. It should direct attention to the importance of all debilitating factors in the life history of the individual, which though disappearing, have created a vicious circle which readily recurs under stress, altering every function of the body, mental and physical.

4. Intravenous Injections of Antimonium Tartaratum in Bilharziosis.—J. B. Christopherson records the results of the treatment of bilharziosis by intravenous injections of antimony tartrate, as seen at the Khartoum Civil Hospital. With the exception of antimony, no drug has yet been found which has the slightest direct effect on the *Schistosomum haematobium* in the portal circulation; antimony tartrate, given intravenously, has a profound effect, however, and as far as subjective or objective signs are concerned, it may be said that a cure is effected in this disease. Whether this cure is permanent or not cannot yet be said, but it certainly lasts for weeks and months. The author states that in the only post mortem examination he knows of in a case which died during treatment, no worms were found in the portal circulation a very few hours after death. In using such a powerful remedy as antimony tartrate, the greatest care must be exercised; it must be remembered that it is a poison and that 2 grains have been known to cause death in an adult. For the present 30 grains should be considered the maximum dose for an adult's course of treatment; if more be required, a second course of injections may be given after some weeks or months.

Substitution of the Thumb by Means of the Great Toe.—R. Mühsam gives the evolution, successive radiographs, and happy functional result of a case in which Nicoladoni's operation was done. The left hand was bound to the right foot, the transplant of the great toe was accomplished in several stages, complete separation being realized on the twenty-fourth day. Two days later the new thumb was warm and sensibility was complete. Ten days later dry gangrene of a portion of the grafted digit arose, involving the ungual phalanx. After elimination of the sequestrum a cure was obtained with functional use of the restored hand. The patient could close the fingers with considerable force, could shave himself (the right arm was amputated). The sensibility, which had disappeared in the necrosed area, had returned completely in the grafted digit at the time of publication.

The Formation of a Prehensile Hand Deprived of Fingers.—C. Ritter refers to Krukenburg's operation, consisting in the separation of the anterior portion of the forearm into two flaps, the radius and ulna being each covered by cutaneous flaps. Prehension is obtained between the two bones, which are separately mobile. Ritter believes that this procedure can be extended to cases where the metacarpus has been preserved. The separation is accomplished between the thenar and hypothenar, and carried up between the two bones of the forearm. Thus two long levers are formed which will be eminently useful in the prehension of various objects.

A New Radiological Symptom of Gastric Ulcer.—J. Schütze considers the presence of denticulations on the left side of the radioscopic shadow of the stomach when filled with an opaque mush as a sign of a single or multiple ulcers. These denticulations, which were formerly regarded as small waves of contraction, are to be looked upon as a regional spasm which has as effect the folding of the gastric mucosa over a certain area. The opaque content in the stomach naturally reveals these folds. This symptom is likewise encountered in certain cases of cholecystitis, but only infrequently. Therefore, this fact does not detract from its value in the diagnosis of gastric ulcer.

October 29, 1918.

Homogentisic Acid as a Chromogenous Product.—G. Katsch has observed a child with advanced rickets whose urine turned to a brownish-black color after being exposed to the air. The writer relates his experiments of oxidation of this urine, and according to the intensity of the oxidizing process a brownish-black, red, reddish-yellow, or yellow color could be obtained. An intensive oxidation discolorized a solution of homogentisic acid and caused this product to disappear by dissolving it. This process gives off a volatile iodophile substance which is not acetone. The writer supposes that the homogentisic acid is dissociated in the body by a process of fermentation due to tyrosinases. This reasoning tends to explain the genesis of melanine. The writer next examines the theoretical reasons for the accumulation of the brown color (ochromose) in the cartilaginous and connective tissues.

The Advantages of Combined Serum Treatment in Diphtheria.—F. von Dellbrück delivers an energetic plea in favor of the combined treatment of diphtheria, that is to say, the simultaneous use of the endovenous and intramuscular injections of the specific serum. By the intravenous route the therapeutic effects are more rapid. As a foundation of his argument for this method of treatment, the writer publishes a statistical table of cases treated by this method and those treated in the usual way. Some of the temperature charts illustrate the antipyretic effect of the procedure. While serum given by intramuscular injections will not prevent suffocation from taking place during the first three or four days, the intravenous route will do away with the danger of this complication after the lapse of forty-eight hours. After two days all danger in this respect can be excluded. Katsch, in his enthusiasm for intravenous treatment, does not hesitate to regard intramuscular injections in cases of septic diphtheria, to the exclusion of the endovenous route, as a very grave therapeutic mistake.

Deutsche medizinische Wochenschrift.

October 31, 1918.

Experimental Studies on the Salvarsan Treatment of Spirochetal Diseases.—W. Kolle, in this article continued from the previous issue, takes up the clinical application of the principles exposed in the first part of the paper. The salvarsan-silver product is particularly remarkable in its action which is especially manifest by the very rapid disappearance of the Wassermann reaction. For that matter, the silver ion itself, even when not combined with salvarsan, has a very powerful effect on experimental syphilis in the rabbit. Salvarsan-silver changes the qualities and brings about a return to the normal of the syphilitic cerebrospinal fluid in all stages of the disease, including general paralysis. From the viewpoint of its secondary effects, this product has up to date shown itself completely innocuous. The product called 1495, of which he absurdly fails to give the formula, is more active in action on the spirillum of recurrent fever than the salvarsan products. As this product does not undergo any change in the state of solution it may render great service in armies. It possesses the advantage of not decomposing when exposed to the air with the same rapidity as neosalvarsan, for example. Turning to the question of complications resulting from the use of certain salvarsan products, Kolle divides them into three groups: (a) the effects of shock; (b) the effects due to hypersensibility, either primary or acquired, in respect to the toxins or oxidation; (c) effects due to too large doses or to the use of too toxic preparations. Certain symptoms of the post-salvarsan accidents are to be classed

among accidents arising from anaphylaxis, while, irrespective of the dose, the interval of time elapsing between the injections must enter into consideration. As to posology, Kolle proposes twenty-five centigrams as a maximum dose of salvarsan-silver and forty centigrams for Ehrlichs salvarsan.

Salvarsan-Silver-Sodium and the Sulphoxylated Product (No. 1495) in the Treatment of Paralysis.—R. Weichbrodt does not come to any fixed conclusions. The products lauded by Kolle did not result in bringing about any permanent improvement, in spite of the fact that a remission in the clinical manifestations did occur.

Treatment of Syphilis with Salvarsan-Silver.—O. Fabry gives unlimited praise to Kolle's product. The spirochetae disappear after a few injections at the dose of twenty to thirty centigrams. There is a rapid disappearance of the clinical manifestations of the disease in all three periods. No accidents from the product have been observed.

Revue médicale de la Suisse romande.

November 20, 1918.

Clinical Observations on the Grippe.—Betchov discusses various aspects of the disease, as plurality of virus, incubation, rachialgia, and bradycardia. In regard to the various bacteria seriously accused as pathogenic, the author includes the Koch-Weeks bacillus. Concerning the filtrable virus the author claims that the latest experiments do not seem to prove its full pathogenicity. The claim had been made that inhalation of this virus could provoke the full disease, but this has not been made good. In the face of so much confusion and contradiction the bacteriologist must for the present be sidetracked for the clinician. The disease, as conceded, has a distinct physiognomy which renders it unmistakable in the absence of bacteriological proofs. The fact has developed in Switzerland that high altitude sanatoria furnish exceptional opportunities for this kind of study. We know that the per cent. of atypical cases is extremely small and that in general cases run true to sample. Of methods of identification the fever curve is important. There is a so-called double thermic invasion, each member of which is accompanied by its own set of symptoms, and this behavior can be explained only on the supposition of two viruses. The first appears to be in operation at the outset and is accompanied by reactions of the upper mucosae and the various aches and pains. This phase is followed by a spurious convalescence which in turn is succeeded invariably by a bronchial localization. This remission of fever causes a V-shaped gap in the temperature curve. It is not unlikely that the first of the viruses which causes the initial rise and other coincidental phenomena is the filtrable virus, the existence of which is beyond doubt. The virus which causes the reappearance of the disease as bronchitis may be one of a large number. Is this bronchitis a complication or sequela or an integral part of the disease? Without doubt the latter, since it is best on account of its great frequency to regard the case without it as abortive. We are familiar with the double virus action in measles and scarlatina, to say nothing of other maladies. Extremely rapid propagation also suggests this origin. Of secondary virus, while Pfeiffer's bacillus plays a rôle, the pneumococcus is believed to surpass it in causing morbidity. In the author's sanatorium the incubation period was repeatedly shown to be 48 hours. Rachialgia is a marked symptom of onset as bradycardia is of convalescence.

Remarks on Epidemic Grippe.—Jeanneret-Minkine first defines grippe as we knew it from the pandemic of 1889 as an acute infectious malady which is due to Pfeiffer's bacillus and which spread from Russia over Europe and the world. It tends to persist in the endemic state. Its ravages are most severe in the old. So far from conferring immunity the victim is if anything more predisposed to second attacks. This, of course, may all be quite true, but it does not apply to our epidemic of to-day in any particular. In Switzerland at least the aged have enjoyed immunity despite their tendency to bronchial affections. It was moreover a common spectacle to see a mother of mature years escape infection while caring for a whole flock of infected children. In the present epidemic Pfeiffer's germ was found by the author in but 7 out of 32 cases and in 3 of the 7 the lungs had been attacked secondarily. Nevertheless, we can read the older epidemic in such manner that it can be plausibly regarded as a mild type of the present one. If there was no plague of pneumonia it is at least true that the pulmonary bases were commonly congested. This phenomenon supervened about the fourth day. Before that the incubation period, fever and participation of the upper mucosae suggested the same filtrable virus. On the other hand these epidemics have nothing in common with endemic pseudogrippe. This is not an integer but a congeries of various affections artificially grouped to constitute one disease. This bastard disease may attack a subject who has gone through true influenza but the last named does not attack a man twice, at least in the same epidemic. Endemic grip should be termed "febrile tracheobronchitis" to distinguish it from influenza. Naturally it is extremely difficult to distinguish between mild influenza in an epidemic and febrile tracheobronchitis, our only resource being absence of contagion in the latter. The author saw no case of influenza that could not be traced directly to another case. Pfeiffer's bacillus is known to superinfect in both whooping cough and tuberculosis. In regard to epidemiology there is no evidence of spontaneously augmented virulence. Influenza may creep about insidiously until it finds a special soil in which it luxuriates. Passing rapidly from man to man, of course, makes it more virulent. The pandemic of 1889 was more severe than that of 1848, perhaps because facilities for rapid communication were less developed. By the same token the next pandemic of the remote future may be more deadly than the one from which the world is suffering at the present time. Finally the author is able to prove that an attack of epidemic influenza causes true immunity, perhaps permanent.

Correspondenz-Blatt für Schweizer Aerzte.

November 30, 1918.

Large Doses of Camphor, Especially in Influenza.—Professor Feer of Zurich gives full credit to Seibert of New York for originating the camphor treatment of pneumonia in 1909. His recommendation was by no means ignored, for various clinicians in different parts of the world have since used the same remedy for that disease. Cases are cited in which huge doses were given without accident—for example, a man of 60 took 74 grams in 11 days. Ever since Seibert's first announcement the author has treated cases of severe pneumonia in children with the method in question. It was certain that the remedy was well tolerated and that in certain cases it antagonized the disease. He later receded from this plan but only because the mild character of the disease in childhood hardly requires such treatment unless there is a demand for the stimulant action of the drug in cardiac and vasomotor weakness. Only when the severity of the present pandemic became apparent did the author, in search for a remedy for bronchopneumonia recur to camphor. But while in the severest type of case the destruction of the lung showed that no treatment could have prevailed the other cases would perhaps have recovered in the absence of camphor. In addition to the latter caffeine and digitalis were given. In a few cases of bilateral pneumonia camphor alone was used and the results were satisfactory. Here there seemed to be a special tolerance for the drug so that massive doses could be given. Since bronchopneumonia is really an affection of adults in this grip epidemic, the author would test camphor in these cases, fully realizing that its reputation is based on results in croupous pneumonia. On that account too much should not be expected of it. In the individual case the author has seen the cyanosis recede at once after an injection. Evidently camphor is only a symptomatic and not a curative remedy, for its effects are chiefly those of a temporary roborant. It appears that the usual dose of this drug can be increased many fold so that no other heart stimulant is required.

Book Reviews.

RATIONAL HYDROTHERAPY. A MANUAL OF THE PHYSIOLOGICAL AND THERAPEUTIC EFFECTS OF HYDRIATIC PROCEDURES AND THE TECHNIQUE OF THEIR APPLICATION IN THE TREATMENT OF DISEASE. By J. H. KELLOGG, M.D., L.L.D., F.A.C.S., F.R.S.M., etc., etc. Sixteenth Thousand. Battle Creek, Mich. Modern Medicine Pub Co., 1918.

THIS volume is the fourth edition of the work with same title published in 1901. The amount of space and number of illustrations are slightly increased, because of the addition of a chapter on recent advances in hydrotherapy. The remainder of the work seems practically unchanged, which is no more than would be expected of a subject like hydrotherapy which can hardly be called a rapidly advancing or evolving branch of therapeutics. Among recent advances are enumerated the Murphy drip and our knowledge regarding the relations of hydrotherapy to blood pressure and arteriosclerosis.

STATISTICAL MANUAL FOR THE USE OF INSTITUTIONS FOR THE INSANE. Prepared by the Committee on Statistics of the American Medico-Psychological Association in Collaboration with the Bureau of Statistics of the National Committee for Mental Hygiene. New York City, New York, 1918.

THIS little pamphlet has a most praiseworthy aim, namely, the promotion of a standard nomenclature for mental disorder. The system it recommends is a result of the combined activities of the American Medico-Psychological Association and the National Committee for Mental Hygiene, and is a very good one. Its universal adoption would bring about a state of affairs infinitely superior to the present one, although many of us would disagree with some features of it. Valuable suggestions are also included for the use of state hospitals in preparing their statistics.

NEUROPSYCHIATRY AND THE WAR. A Bibliography with Abstracts. Prepared by MABEL WEBSTER BROWN, Librarian, the National Committee for Mental Hygiene. Edited by FRANKWOOD E. WILLIAMS, M.D., Associate Medical Director, the National Committee for Mental Hygiene. New York: War Work Committee of the National Committee for Mental Hygiene, 1918.

THIS book is the sort of thing the need for which is often felt but seldom supplied. The literature of America, England, and her colonies, France, Germany, Italy, Holland, and Russia, has been carefully combed for articles and books dealing with psychiatric or neurological aspects of the Great War and these have been abstracted and collected here. The result is of the utmost value and the collectors of it are to be congratulated. The abstracts have been prepared with painstaking care so that in many instances they contain all the information of the original article, but in a more easily accessible form.

INFORMATION FOR THE TUBERCULOUS. By F. W. WITTICH, A.M., M.D. Price, $1. St. Louis: C. V. Mosby Company, 1918.

THIS is a little book intended for the layman who fears to become tuberculous or is already afflicted with the disease. Dr. L. G. Rowntree, Professor and Chief of the Department of Medicine, University of Minnesota, honors the book with a preface in which he makes the statement that "The best treatment, generally speaking, can be obtained from the tuberculosis specialist." This is a beautiful tribute to the specialist, but we question whether it is entirely just to the general practitioner. We grant that a specialist can and ought to be able to make a diagnosis in a difficult case where the general practitioner may have failed, but believe that the average up-to-date practitioner can carry out the "sanatorium treatment at home," if the home of the patient is suitable and the patient and those living with him are willing to do what is necessary.

There are 23 chapters in the book, devoted to the anatomy and physiology of the lungs; bacteriology; symptomatology; therapeutics, including sanatorium régime; climatology; tuberculin treatment; and artificial pneumothorax. The first criticism which the reviewer would wish to make is that in a book entitled "Information for the Tuberculous" to devote 12 pages to the technical description of culture products and then say that not any of them nor any drug "has a selective affinity for the tubercle bacillus and will destroy it in the body without doing harm to the tissues" is to say the least quite useless. All the information needed by the layman concerning such a subject could be imparted in less than one page. Utterly out of place in a popular book on tuberculosis, and even dangerous, is chapter 23, wherein 10 pages are devoted to the definition of the terms "incipient," "moderately advanced," "far advanced," and their subdivisions. Any one familiar with the psychology of the tuberculous will at once say this is the chapter which the tuberculous invalid, or the one who is afraid to become one, will read and reread to the detriment of his peace of mind and subsequent physical welfare. If the author will accept this criticism and omit the chapters on culture products and on definition of clinical terms in future editions, the book will be indeed a valuable one to be placed in the hands of all those seeking or in need of the information it contains.

THE EFFECT OF DIET ON ENDURANCE. By IRVING FISHER, Professor of Political Economy in Yale University, Chairman of the Hygiene Reference Board of the Life Extension Institute. Price, 60 cents net. New Haven: Yale University Press, 1918.

NUTRITIONAL problems have become recently of paramount importance, owing to the Great War and, if we may believe economic experts, will engage the world for many years. America has long been known as a land of ill-regulated diet and food waste. This little volume contains an account of experiments of an eating club of Yale students, under the direction of Professor Fisher. The results obtained may be summarized: The highest efficiency on a reduced diet.

THE NEWER KNOWLEDGE OF NUTRITION. The Use of Food for the Preservation of Vitality and Health. By E. V. MCCOLLUM, School of Hygiene and Public Health, The Johns Hopkins University. Price, $1.50 net. New York: The MacMillan Co., 1918.

WHETHER or not the word "Hooverize" becomes a legitimate part of our language, the understanding of dietetics has been augmented by the Great War. Man has learned to eat, not what he wants, but what will be cheap, compact, and nourishing. In this little book McCollum gives much valuable information about foodstuffs and their dietetic values. Some interesting charts are appended, showing graphically the results of various feeding experiments. Vegetarian diets are discussed and their difficulties and dangers indicated. The book should be read by every one who is in anyway responsible for the choice of diet of other persons.

NEUROLOGICAL CLINICS. Exercises in the Diagnosis of Diseases of the Nervous System. Given at the Neurological Institute, New York, by the Staff of the First Division. Edited by JOSEPH COLLINS, M.D. Price, $3 net. New York: Paul B. Hoeber, 1918.

IT is extremely difficult, perhaps impossible, to become proficient in neurology from didactic lectures or textbook exposition; nothing can take the place of the patients themselves, demonstrated by a competent clinician. Next best is a book such as this which attempts to do for neurology what Kraepelin's book does for psychiatry. The brilliant editor of these studies has written sixteen of them himself and his adroit touch is evident in many of the twenty-five others. The cases studied vary greatly in interest as well as in the skill with which they are presented, as must inevitably be the case in a compilation from a dozen different clinicians. A strict interpretation of the title would exclude Nos. 14, 21, 22, 23, and 24, especially those dealing with dementia precox where the lack of space is most keenly felt. The three patients described in the chapter on obsessions, too, are rather sketchily presented and psychoanalytic interpretations are assumed as true without giving the evidence, a fault much too frequent in the works of that school. The purely neurological chapters are excellent, however, and the general practitioner will find the book as a whole very valuable. The neurologist will add it to his library after one glance at it.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Forty-sixth Annual Meeting, Held in Chicago, December 8, 9, 10 and 11, 1918.

THE PRESIDENT, DR. CHARLES J. HASTINGS OF TORONTO, ONTARIO, IN THE CHAIR.

(*Concluded from page 84.*)

The Program of the United States Public Health Service.—Surgeon-General RUPERT BLUE, U. S. Public Health Service, Washington, D. C., pointed out the need of special vigilance on the part of health authorities in order to prevent the introduction and spread of dangerous epidemic diseases by our returning soldiers. Furthermore, he urged wider interest and a greater participation on the part of the people in public health work. The work of the medical departments of the British, French, and American Armies had shown what could be accomplished by well-planned, thorough-going health measures. When the history of the present war was written, not the least significant part would be that which recorded the achievements in the field of preventive medicine. Anyone familiar with the history of other wars would realize that hundreds of thousands of lives had been saved as a result of the excellent work in sanitation and preventive medicine carried on by the British, French, and American military forces. What could be done among soldiers in the unfavorable environment of war could and should be done among the civilian population in the more favorable environment of peace, and this could be accomplished by intensive health work carried on by the U. S. Public Health Service in cooperation with State and local authorities. Special emphasis was laid on matters dealing with industrial hygiene, on improved rural sanitation, the prevention of diseases of infancy and childhood, and on popular health education. In connection with the last named, the Public Health Service contemplated constituting itself a national center and clearing house for information, advice, and educational assistance on all matters relating to public health and hygiene. The general adoption of the program proposed would not only result in the saving of hundreds of thousands of lives, but would so improve and strengthen the coming generation that the nation would successfully maintain itself in the strenuous competition of the near future.

The National Welfare.—Colonel VICTOR C. VAUGHAN, M. C., U. S. A., stated that the theses proposed in his paper mgiht be condensed as follows: (1) The Federal Government should assume control of certain functions of the educational system of the country. (2) The youth of the country, on reaching a certain age, to be determined after mature deliberation, should be drafted into the service. (3) The only exemptions from this service should be the mentally incompetent. (4) Those suffering with physical defects should be classified, their defects repaired as far as possible, and the training adapted to their individual needs. (5) The period of training should cover a period of two years; it might be continuous or broken into terms. (6) This training should be disciplinary, and to this extent military, but the primary and principal purpose should not be the preparation of men for the fighting line, but for good citizenship. (7) In the writer's opinion, this service would be best administered under the War Department. (8) The training should include the physical, mental, and moral man. (9) Physical development and the practice of personal and community hygiene should be one of the fundamentals. (10) Instruction in the prevention and eradication of infectious diseases should be given by practical demonstration as well as by textbooks and lectures. Personal hygiene must be practised in daily life; it was largely a matter of habit. (11) The English language must be taught, and its correct use demanded of all at all times. (12) The history of our nation, its growth and development, its relation to other nations in time of peace and in time of war, its material resources, and its ideals, should hold an important position in the curriculum. (13) The obligations and duties of citizenship should be impressed upon all. (14) To those lacking in training in the following subjects, proper instruction should be given: (*a*) Mathematics, (*b*) physics, (*c*) chemistry, (*d*) biology; the last mentioned should include the influence of heredity and environment upon the physical, mental, and moral man. (15) Every individual should be given a substantial start in some industrial trade or profession. He should know how to take care of his own body, make a decent living, be a clean and intelligent citizen, and be ready at all times and under all conditions to render effective service to his country. (16) These training schools should be without expense to the individual; he should be housed, clothed, fed, and instructed by the Government, and his family should be moderately compensated for his time; in fact, he should have the status of an enlisted man in the Army. (17) When he completed the courses at the training school he should pass into a reserve corps and should carry a qualification card showing his grades in physical, mental, and moral fitness. (18) In the reserve corps he should be examined at intervals of two years until he reached forty-five years of age; at these examinations his qualification card should be reviewed. (19) From the time of entering the training school through his continuance in the reserve corps, he should at all times carry on his person an identification card, which he should present at the request of a civil or military officer. (20) In addition to the service provided for above, the Federal Government should improve the efficiency and extend the functions of its Health Service. (21) The registered area should be extended so as to embrace the whole country. (22) Morbidity statistics should be collected on uniform cards. (23) The hygienic laboratory of the Public Health Service should be developed and opportunity should be given for the multiplication of research investigations. (24) Both preventive and curative medicine should be placed at the service of all citizens; it should be socialized. (25) Every community should have a health commissioner and such personnel as might be necessary, with hospital and laboratory adjuncts. (26) In previous documents which were written by those who founded our government, many wise provisions were found, two of which he quoted: (*a*) "All men are born free and equal." (*b*) "Religion, morality, and knowledge being necessary to good government and the happiness of mankind, schools and the means of education shall forever be encouraged." These principles should be added and our descendants urged to strive to realize them: "(*a*) Equal opportunity for self development shall be provided for all. (*b*) No ill which human skill can relieve should be permitted to continue among our people."

Venereal Disease Control.—Dr. JOHN DILL ROBERTSON of Chicago stated that the city of Chicago secured an ordinance requiring the reporting of venereal diseases on June 29, 1917, the ordinance being practically in the form of the Australian law. It required that: (1) The physician must report all cases of gonorrhea, syphilis, and chancroid. (2) The physician must give the patient an educational circular. (3) In case the patient changed physicians, report must be made to the previous physician. (4) Failure to continue treatment must be reported to Health Department in ten days. In the first ten months of 1918, 5,258 cases of venereal disease were reported to the department. Known prostitutes were arrested by the police and brought to the Iroquois Memorial Hospital for the purpose of securing specimens for examination. When brought into court the women obviously guilty of crime were sentenced to the House of Correction; others found infected were turned over to the Health Department and sent to the Lawndale Hospital. Of 480 males admitted to the House of Correction in November, 1918, 6.25 per cent. were suffering with venereal diseases and 11.6 per cent. of the females. Of 300 women admitted to the workhouse in Cleveland, 65 per cent. had venereal diseases, and of the males examined at the same time, 35 per cent. had venereal diseases. He thought it safe to say that not more than 1.5 per cent. of the population of Chicago was suffering with infectious venereal diseases. A municipal venereal disease clinic was absolutely essential for the enforcement of a venereal disease ordinance. At the Chicago clinic 630 men and 91 women were treated from January 1 to November 1, 1918. A municipal venereal disease hospital was another essential. During the first ten months of 1918,

Chicago treated 325 women between the ages of 15 and 53 in such a hospital. These women were kept occupied at such work as they were capable of doing. Statistics were obtained as to mental condition, educational status, and occupations claimed by them. Morphine users among them were given treatment. Complete medical statistics were obtained from the hospital record card, which was especially evolved for the use of this hospital by the Chicago Health Department. Thirty-nine per cent. of the women under consideration had hooded clitoris, which suggested a possible first predisposing cause for delinquency. Laboratory findings on specimens from patients showed 159 with syphilis positive, 127 gonorrhea positive, 12 with mixed infection, 27 nonvenereal. Education and the "big stick" were both necessary to the enforcement of a venereal disease ordinance. Quack advertisements to the number of 1,500 were removed in Chicago and 3,500 educational posters substituted. Druggists were educated against counter prescribing. With the absolute and full cooperation of the physician and the druggist venereal disease could be as effectively controlled as tuberculosis.

Lipovaccines with Special Reference to Public Health Work.—Colonel EUGENE R. WHITMORE of Washington, D. C., said that protective inoculation was one of the important methods of prevention of infectious diseases. In using bacterial vaccines in protective inoculation, it was necessary to use a rather large amount of bacterial material to obtain practical protection. With the saline suspended vaccines, it was necessary to give the vaccine in several doses, as the general reaction was severe if the entire amount was given at one time. The necessity of giving repeated doses made it difficult to carry out protective inoculation on a large scale, even when only one disease was considered. When attempt was made to vaccinate against several diseases, the repeated doses made such vaccination impossible. The body could elaborate antibodies against several pathogenic bacteria at the same time; but when attempt was made to include more than one organism in a saline vaccine, the dose of each organism had to be reduced below what was considered necessary to give protection. Another objection to saline suspended bacterial vaccines was that there was rapid autolysis of the organisms in the saline solution, and it was not advisable to use the vaccine after it was over three or four months old. French investigators showed that it was possible to inject large amounts of bacterial material suspended in oil, without producing severe general reaction. This was due to the slow absorption of the bacterial material in the oil, and to the detoxifying action of the oil. They also showed that the immunity response was as good after injection of the entire amount of bacterial material at one dose suspended in oil as when it was injected in divided doses suspended in saline solution. They also showed that the bacteria remained in the oil for at least eight months without undergoing any change. The French investigators obtained satisfactory results with a T. A. B. vaccine suspended in oil; and they gave the name lipovaccine to these vaccines. In the United States Army, a number of lipovaccines had been prepared; and the triple typhoid lipovaccine was now the official vaccine in the army. A pneumococcus lipovaccine was being used in the army, and meningococcus, dysentery, cholera, plague, and streptococcus lipovaccines had been prepared and tried out. The lipovaccines had the advantages that the entire amount of bacterial material could be given at one dose, without severe general reaction, and the immunity response was at least as good as where the bacterial material was given in divided doses suspended in saline solution. The lipovaccines kept for at least eight months. It was considered that these advantages were of importance in public health work. The lipovaccines were probably not adapted to use in therapeutics. It was necessary to guard against attempting to adapt the advantages of the lipovaccines to the preparation of shotgun vaccines.

Industrial Disease Administration at the Present Time.—Dr. EMERY R. HAYHURST of Columbus, Ohio, stated that several important problems were at hand in adjusting health administration to cover industrial diseases and hygiene at the present time. There were: (1) keeping the workers able to work; (2) providing for increasing numbers of women, older people and youths; (3) maintaining all sanitary regulations; (4) watching especially against fatigue; (5) maintaining not only average vitality but raising the average vitality; (6) counteracting the indifference promoted by personal prosperity, number of available jobs, etc., and (7) continuing the spread of fundamental information calculated to save human waste—so-called hygieiology. Neither war nor peace had discovered many new forms of human waste. They had, however, uncovered to the world the necessity of and the possibilities in industrial hygiene. Expansion was the principal adjustment. One establishment in Ohio employing over 5,000 women increased its output ten per cent. almost over night by giving heed to advice from the State Department of Health on temperature and humidity control in the work-rooms and at the same time cut down remarkably absences, quittings, and a peculiar form of sickness which was spreading through the plant. Such might be done in many other establishments. The war had put sanitation and hygiene upon a firm basis in the public's opinion. Advantage should be taken of this in industry. Shortage of hygienists and sanitarians to meet the demands was acutely felt and it was necessary for certain properly equipped schools or the Federal Public Health Service to select and instruct by short courses a large number of engineers, sanitarians, and physicians in the principles of industrial hygiene and diseases. A result of the great war was that a thousand people now really saw the point of workplace sanitation and personal hygiene, to one person a couple of years ago. Plenty of knowledge was at hand and needed only to be applied.

Modern Advertising and the Nostrum Evil.—Dr. ARTHUR J. CRAMP of Chicago said that the evils connected with the sale of medicinal preparations of the home remedy type—the so-called patent medicines—were due to proprietaryship and to the advertising methods that such proprietaryship engendered. The perpetual proprietary monopoly which the patent medicine seller obtained by means of our trade-mark laws made extensive advertising profitable and, together with secrecy of composition, had led to the gross abuses which had made the patent medicine business a menace to the public health. The man who advertised and sold a patent medicine had an important commercial advantage over the seller and advertiser of general merchandise. The former had nature working in his interest; the latter had nature operating against him. The man who sold a suit of clothes or a piano or an automobile had natural forces (as expressed in wear and tear) as his competitor; the man, on the other hand, who sold a patent medicine had the forces of nature as an assistant. Those selling remedial agents not only had the advantages of making a lucky fluke but also had the much greater chance of being given credit for results to which their remedies in no way contributed. Modern advertising differed from its earlier prototype in that whereas the latter chiefly, if not exclusively, notified the public simply where and how its demands might be supplied; the former was based largely on the principle of creating demands for the products advertised. In the case of general merchandise there might be some excuse for these attempts to create in the minds of the public a desire for certain things it would not otherwise want. No such excuse could be put forward in favor of the sale of medicaments. No man had any moral right to so advertise as to make well persons think they were sick and sick persons think they were very sick. Such advertising was an offense against the public health. Modern medical advertising by the skillful use of testimonials, by plausible claims, direct or inferential, led the public to magnify every trivial ailment, deceived those who were well into the belief that they were sick, and impressed the idea that the products were panaceas for whatever ailments the public was suffering from or could be deceived into believing itself to be suffering from. Medicaments of the home remedy type for the self-treatment of simple ailments should contain no dangerous or habit-forming drugs; should not be recommended for diseases that were obviously too serious to be self-treated; should be non-secret, and should not be sold under false claims, or so as to make the public magnify trivial ills and dose itself unnecessarily. There

were plenty of official products (U. S. P. and N. F.) to meet every legitimate requirement for medicaments for self-treatment. These products were non-secret; their purity was established and protected by law. As any competent pharmaceutical house could make them, the elements of secrecy and proprietaryship were removed, and the incentive to fraudulent or misleading advertising claims was abolished.

Compensation for Vocational Diseases.—Dr. Frederich L. Van Sickle of Olyphant, Penn., said that the foundation of industrial insurance was built upon the man who employed, the society which fostered, the government which wished to protect the men or women who must earn their own living and that of a family by daily occupation at some employment, and the desire so to remunerate that worker during a period of disability as to effectuate the income. This foundation was only as substantial as the conscientious endeavor of the employer; the municipalities and the State should surround it with security and with equitable fairness to the employee. If industrial insurance was a feature of industry, which must exist in the United States, for the purpose of making happy, making content, making self-prosperous, making efficient the working people of the United States, it should be the endeavor of all right-minded people in every walk of life, who in the sum total must bear the added burden of any insurance feature which should be placed upon the product of any industry in its ultimate result, to see that it was made a proper and substantial measure. Fundamentally, it would make very little difference to the manufacturer whatever added cost were placed upon any industry in order that insurance might be carried, premiums paid, awards made in cases of disability, competent medical and surgical nursing and hospital facilities supplied, provided no complaint were made upon the part of the ultimate consumer relative to the added costs thereby incurred. Our solution then of the problem of compensation as it related to vocational insurance must be first rated upon the hazards of the industry, upon the needs of the worker and upon the facilities supplied to care for him or her in a disease or condition arising from that vocation. There could be no question as to the equitability of a protective insurance as it related to sickness, as well as its relation to workmen's compensation in injury in our present every day thought from an American viewpoint. Prolonged disability in civic life was not included in a discussion of compensation in diseases but was well known to physicians, where the individual desired to escape the responsibility or necessity of employment. The limit of twenty-six weeks in any one year had been an old standard in many states, in lodges and societies, which no doubt was a fair limit of time when we considered that on an average not more than nine days per year was lost by each individual worker in industry, due to sickness. A closer relationship with the medical profession in a discussion as to the methods of application of social insurance as it related to sickness must obtain with employers and representatives of labor, in that a modern American plan of application be arranged, in order to make it a success in this country. Members of the medical profession, as a rule, were reasonable men and women, willing to give much of their time and their talent without compensation, which had been proven from hospital statistics. It could not and should not be expected of the medical profession so to rearrange the application of their daily work, if it produced so changed a plan, in the application of insurance for vocational diseases, wherein they were not familiar or willing to accept the plans and provisions as made by assemblies, without voice or vote on the part of the physicians. The compensation to medical men and women must be proportionate to the skill required in the treatment of particular diseases arising from any particular industry, and the facilities offered by the employer for having such treatment properly administered, so that efficient results might be obtained. He maintained that the same provisions should be incorporated in every act, whether for disease or for injury, that the fees obtained in a like community for such services rendered to the individual should be the fees paid in either compensation for injury or in sickness insurance or in vocational disease insurance.

Tuberculosis Control Following War Conditions.—Dr. D. B. Armstrong of Framingham, Mass., stated that the war would undoubtedly increase the magnitude of the tuberculosis problem in the United States, just as it had in foreign countries. From the first draft alone there were returned to civilian communities 50,000 cases of hitherto undiscovered tuberculosis. In England and in the other warring countries the tuberculosis death rates had shown decided increases since the war began. In 1913 the death rate from pulmonary tuberculosis in England and Wales was 101 per 100,000 people living. By 1916 this had increased to 118 per 100,000. In Birmingham alone, for instance, the 1913 rate of 119 per 100,000 had increased in 1917 to 130 per 100,000. As a result of the special tuberculosis work being done under the auspices of the National Tuberculosis Association in Framingham, Mass., they already had in this community excellent evidence to show that tuberculosis existed in the civil population to a greater extent than had hitherto been supposed. In Framingham, which was a typical industrial town with average health conditions, there were on January 1, 1917, twenty-seven known cases of tuberculosis. After an extensive search for tuberculosis the number of living known cases was increased to 181 in November, 1918. An intensive examination of about two-thirds of the population of this New England town had shown that approximately 2 per cent. of the people had tuberculosis in either an active or an arrested form. This meant that in the United States as a whole there were 2,000,000 cases of tuberculosis, and at least 1,000,000 people who had the disease in an active and possibly contagious form. The Framingham work was financed by the Metropolitan Life Insurance Company. How were we to meet this national problem? In the first place, it meant adequate appropriations for general health and anti-tuberculosis work among infants, in schools, in factories, etc. Where we had been spending 15 cents or 25 cents per capita on health work, we must spend from $1 to $2 per capita if we were going to meet our obligations. As to tuberculosis in particular, it was important to find the early cases and to get them under adequate treatment. The provision in Framingham of an expert medical consultation service for the local practising physicians had greatly increased the discovery and reporting of the disease. The early cases as well as the arrested cases could adequately be cared for at home if satisfactory nursing arrangements were made. Finally, the public at large must be educated more intensively than hitherto regarding the principles of hygienic living. The necessity for the health of the civil population was one of the lessons the war had taught us. We had gloriously won the war. The extent to which we were successful in applying the hygienic lessons of the war to our civil population was one of the measures of a glorious and victorious peace. As Dr. Livingston Farrand, the head of the American Red Cross Tuberculosis Commission in France, said, "To make our country really safe for democracy, we must first make it healthy."

The Work of the Department of Health and Sanitation of the United States Shipping Board.—Lieutenant Colonel Philip S. Doane, M. C., U. S. A., Director of Health and Sanitation, United States Shipping Board Emergency Fleet Corporation, said that the United States Shipping Board Emergency Fleet Corporation, through its Department of Health and Sanitation, was maintaining supervision over the health of about 430,000 employees, building ships in 171 yards scattered over 7,000 miles of coast line. Like all war emergency industries, the Shipping Board had to organize its various departments in such a manner as to meet peculiar needs. It was more than a year after its organization that the need of a department of health and sanitation was felt by the board. As in all new war industries, there were no precedents established here. The needs, moreover, of the shipyards from a health and sanitation standpoint were varied and peculiar. The problem confronting the Department of Health and Sanitation of the United States Shipping Board Emergency Fleet Corporation was to secure such conditions in shipyards and their environment as to maintain the workers in the healthy, vigorous condition so essential to speedy construction of ships. Arrangements were made with local hospitals for the care of injured employees. Yards employing over 10,000 men, without the nearby

hospital facilities, had their own hospital. These hospitals were constructed according to plans and specifications outlined by the Army, with suitable modifications. The surgical care of injuries was given special attention. Minor accidents were very numerous in a shipbuilding yard. All employees were urged to report for dressing with every injury, no matter how slight; consequently the monthly reports showed a percentage of injuries often running as high as 50 per cent. of the men employed. The use of dichloramine-T was strongly recommended in the yards. Experience had proved that the use of dichloramine-T was both efficient and economical, but that it must be used correctly or the desired results were not obtained. The board was cooperating with the Surgeon-General of the Army, the Surgeon-General of the Navy, the United States Public Health Service, and the Committee on National Defense in carrying on a prophylactic venereal campaign both in the shipyards and in the cities and towns surrounding them. The educational campaign in the yard was conducted by enlightening lectures given by men of experience, assisted by lantern slides, drawings, and charts. This campaign was becoming so general in character that State laws were necessarily being enacted to favor this work. The efficiency of the ship workers had been markedly interfered with in many cases by venereal diseases. The eradication of mosquitos was an important measure at shipyards. This department cooperated with local and State health authorities to obtain suitable drainage of the yard and its environment, filling in low land, oiling stagnant water, etc. In mosquito countries screening of buildings and sleeping quarters was urged, using normally No. 16 mesh. Where the yellow fever mosquito might be bred at least No. 18 mesh was required. Insanitary conditions often existed to a marked degree in towns and cities in which the shipbuilder must live. Having no jurisdiction in these premises, it became necessary for them to call upon the State or civic health boards to assist in carrying on their work. The country at large recognized the necessity of the ships and they had but to make the request for assistance when every possible agency seemed more than willing to do its part. The department's every resource had just been put to the test when the socalled influenza epidemic attacked the shipyards. The Fore River yard at Quincy, Mass., just outside Boston, was the first yard seriously affected. The disease then spread to all the yards along the northeastern coast line, then to the large yards in the Delaware River region, then west and south, and last of all to the yards in the Great Lakes region. It was strange that the Pacific Coast yards should have been affected before those of the Great Lakes region. They were proud to note that, owing to the efficient action of the medical and sanitary experts, not a single shipyard had been compelled to shut down.

New Evidence on the Cause of Human Tuberculosis.—Dr. BURTON R. ROGERS of New York City stated that childhood was now almost universally recognized as the age when the bulk of the primary tuberculous infections occurred, even though symptoms might not appear or death occur until twenty or more years later. The two paramount conditions of babyhood and childhood were close association with parent and the milk drinking period. In spite of the prevailing opinion, with all the evidence in, final analysis might some day prove that milk-borne infection of bovine origin was and had been the principal factor in the primary cause of human tuberculosis. The American Public Health and National Tuberculosis Associations should study all methods and make recommendations as to the best methods so as to secure the greatest and quickest returns from the vast appropriations that were and would be made, if for no other purpose than to eliminate the controversial problem of intertransmission, and at the same time whatever human tuberculosis might be of bovine origin. Was tuberculosis really a city disease? Take Crawford County, Ind., near the human population center, for instance, which was the blackest and worst county in that whole State for human tuberculosis. Marion County, in which Indianapolis was located, the four times largest city, yet stood only fifth in a tuberculosis death rate—and this might be due to the slum conditions of a present or past period in the surrounding dairy zone rather than slum conditions in the homes. Crawford County had 304 square miles of outdoors. Less than 13,000 people lived in the county. They were scattered on 1,861 farms and in twenty-one towns and villages. The largest town contained less than 1,200 people. It was doubtful if there was a three-story tenement in the county, and if every house was not at least 10 feet from every other house, and some several miles apart, and if every living and sleeping room had not one or more outside windows. These were certainly not city conditions. Yet in a six-year period (1909-14) 24 per cent. of the human deaths in this county were due to tuberculosis. It was possible that, instead of the vast expenditures for human tuberculosis sanatoria, hospitals, and dispensaries, in the long run, it might have been better to have bought or leased farms and barns and mobilized the tuberculous cattle—not for the sake of and in the interests of the cattle *per se* or other cattle and animals or their financial owners, but so their products could knowingly and intelligently be made safe and even therapeutic—because virulent tuberculous cattle unconsciously scattered in an immense number of unknown herds were infinitely more dangerous than if knowingly concentrated on a few known farms, for such scattered cattle might menace more human beings than might those tuberculous people who had been, were now, and would be mobilized in human tuberculosis sanatoria. Indeed, the sacrifice of human life involved should justify the Association seriously considering whether the risky arbitrary standard, practically unchanged since 1898, based solely upon deductions from variations in simple shape or morphology and cultural modifications of the tubercle bacilli after they had grown for some time in different species, and perpetuated after implantation in dead non-resisting test-tube media, should not be substituted for a newer and certainly safer standard, viz., the unquestioned effect of the tubercle bacilli of herbivorous bovine origin upon the living resistant omnivorous hog, a much nearer approach to man or babies, than a dead non-resisting test tube ever could be.

Democracy and Public Health.—Dr. CHARLES J. HASTINGS of Toronto, President of the Association, said that every nation that permitted people to remain under the fetters of preventable disease and permitted social conditions to exist that made it impossible for them to be properly fed, clothed, and housed so as to maintain a high degree of resistance and physical fitness, and that endorsed a wage that did not afford sufficient revenue for the home, a revenue that would make possible the development of a sound mind and body, was trampling a primary principle of democracy under its feet. Equal opportunity for all was the underlying principle of American democracy. Good health was the foundation of a strong nation. No nation could afford to neglect it or to ignore the lessons taught by the absence of a reasonable degree of physical efficiency.

Team-Work in Public Health.—Dr. GEORGE E. VINCENT, President of the Rockefeller Foundation of New York City, stated that the work of the fifty-seven health societies of the United States was to a large degree unsuccessful because too much time was spent in the collection of funds and preaching about accomplishments, thereby leaving no time for scientific investigation. It was certain that so long as the voluntary agencies of public health of this country persisted in the present policy of isolation and rivalry, seeing their specialties out of focus, unconsciously misleading the public, hampering the development of unbiased research, preventing the consistent and careful education of the people, they would be in no position to bring to bear upon the Federal Government pressure for the creation of a Federal department of health with a secretary in the President's Cabinet. Three things were necessary to correct these evils: (1) The establishment of a definite body of scientific knowledge. (2) Effective demonstration of the application of such knowledge. (3) Systematic, unified, consistent education of the public in the scientific basis of health and the principles of procedure.

The Future State Policy in Relation to Health and Welfare.—Mr. FREDERICK L. HOFFMAN of Newark, N. J., stated that a beginning had fortunately been made in this country through the Children's Bureau at Washington to initiate a plan for the systematic

measurement of children of preschool age, subsequently, no doubt, to be followed by the introduction of systematic measurements of children during the teaching period from the primary grade to the university. It was true, of course, that vast numbers of children were being measured in school and out, and that equally vast numbers of measurements were made of young persons in industry or in the military service, etc. The lamentable fact, however, was that these measurements were, in the first place, crudely made, and, in the second place, the prevailing standards of normal height and weight, chest expansion, etc., were seriously deficient in scientific accuracy; and in the third place, the ascertained deficiencies, or departures from the normal, were not made a matter of serious concern on the part of the school or the parents, or the medical profession, or all combined. The second prerequisite for a rational and effective public health administration was the accurate and complete registration of all serious illnesses, whether in private practice or in institutions under medical supervision and control. The third fundamental principle of modern health administration was a thoroughly well worked out State medical service, including under the term all of the medical services now rendered in connection with public institutions, poor-law establishments, schools, State and municipal dispensaries, clinics of all kinds, etc. The proposed administration would seem to group itself into three main divisions, each of which should be in charge of an assistant federal health administrator, as follows:

Division A. *General Public Health and Quarantine.*—Section (1) Health organization and administration. (2) Health laws and ordinances. (3) States relations service. (4) International and war time quarantine. (5) Communicable and transmissible diseases. (6) Urban sanitation, town planning and housing. (7) Rural sanitation. (8) Sanitary engineering and drainage. (9) Tropical medicine and sanitation. (10) Hygienic laboratory. (11) General scientific research.

Division B. *Medical Practice and Physical Welfare.*—Section (12) Medical practice, pharmacy, and dentistry. (13) Physical anthropology. (14) Child hygiene. (15) School hygiene. (16) Personal hygiene. (17) Industrial hygiene. (18) Mental hygiene. (19) Social hygiene. (20) Hospitals and institutions. (21) Race pathology.

Division C. *Statistics and Information.*—Section (22) Mortality statistics. (23) Morbidity statistics. (24) Health education, health propaganda, and publications. (25) Associated activities and health promoting agencies.

An Inquiry Into the Reliability of Diagnosis of Diseases Causing Death.—Mr. Louis I. Dublin and Mr. George H. Vanburen of New York City said that in September, 1915, Dr. Haven Emerson emphasized the fact that registrars, life insurance companies, pathologists, and others believed that there was a high percentage of inaccuracy in the statistics of cause of death on account of the correspondingly high proportion of inaccurate diagnoses which formed the basis for these statistics. Dr. Emerson's viewpoint was that, especially in cases where more or less obscure conditions caused death, a good proportion of the diagnoses based on clinical findings were very certain to be wrong. So much interest was attached to the questions raised by Dr. Emerson that the Chairman of the Vital Statistics Section appointed a committee on "The Accuracy of Certified Causes of Death," and this committee was instructed to consider the relation of this subject to mortality statistics and to the International List of Causes of Death. Recommendations covering 189 titles of the International List of Causes of Death were made with a view to separating them into two classes. The first class was made up of those titles which the committee believed should be accepted as representing reports of causes of death based upon essentially reliable diagnoses, without autopsy and without the statement that there were specific supporting data other than clinical findings. The second class consisted of those which should not be accepted as based substantially upon reliable diagnoses, unless it was clear that they were verified by autopsy, pathological findings, or other specific supporting data. This subject the Metropolitan Life Insurance Company decided to be one of sufficient interest to the public health movement to form the basis of a special inquiry to determine the proportion of cases in its mortality experience in which the diagnosis of cause of death might be considered accurate and complete. The information concerning the reliability of the statements of cause of death among its policyholders was secured from the records of mortality during the period of January to June, inclusive, 1918. The findings set forth were based on 64,820 deaths of industrial policyholders. On this basis it was determined that, according to the standards of reliability of diagnosis set down by the eminent clinicians and pathologists who served on the American Public Health Association Committee, 55,372, or 85.4 per cent., of the 64,820 deaths in their industrial experience during the six months covered by this report were definitely and reliably classified as to cause of death. There was little doubt that an estimate of 90 per cent. would not be excessive as the figures representing the ratio of diagnoses that were correct on the basis of the recommendations of the committee appointed by the Vital Statistics Section to study this subject. Dr. Emerson's assumption was therefore incorrect.

Vaccination as a War Measure.—Dr. Maurice Ostheimer of Philadelphia stated that there was not the slightest doubt that smallpox had increased during the period of the war throughout the United States, and in a great many instances the spread of the disease was definitely to be attributed to unvaccinated workers in the industrial plants making munitions. In some instances a migrating unvaccinated worker developed smallpox, gave the disease to one or more workers in one, two or even three plants before he was caught and isolated. In Philadelphia alone up to October 18, 1918, there had been 33 cases of smallpox reported, while there had only been 12 during the entire year of 1917 and only 5 in 1916. He suggested that it might prove practicable for the United States Public Health Service to request of the United States Railway Administration that tickets for places outside of the city be sold only to a purchaser who presented certificates of successful vaccination for each member of his party. It would be an excellent idea to have the Surgeon-General of the U. S. Public Health Service put into practice some method of securing the vaccination of all unvaccinated adults.

The Clinic for Vocational Diseases.—Dr. Louis I. Harris of New York City said the work of the various clinics had been handicapped by the fact that the industrial corporations had been slow in extending this work, not seeing that humanity and profits went hand in hand. Very few of the municipalities up to the present time had done anything in the way of clinical study or of industrial hygiene. Too many of them were held back by the fear that it meant elaborate equipment, when what was really needed was enthusiasm and social vision and the knowledge that a man who carried a stethoscope, a blood pressure instrument, possibly a tongue depressor, and such equipment as was possessed and carried by every doctor in his rounds, plus common sense and a knowledge of the diseases the industrial environment might either directly produce or predispose to, was splendidly equipped to go into a factory and extemporize a clinic in any spare room that was well lighted and free from noise. This traditional idea that to do anything we must have elaborate outfit and budget had retarded progress in many communities of an industrial character. In the City of New York less than 200 cases per annum, about 178, of occupational diseases were reported by all the 8,000 doctors, all the hospitals and dispensaries and all the industrial corporation physicians. This must reflect either ignorance or indifference or limiting of social vision. This too was but an infinitesimal fraction of the number of cases which would subsequently be registered as tuberculosis cases, as cases of all kinds of occupational poisoning, and the things in which the occupational factor would never be recognized. The vocational clinic in New York gave to the poor man in the community, whom the health authorities were obligated to protect, the type of protective medical care which had up to the present time been enjoyed only by the rich who could consult their doctors at frequent intervals to learn as to their physical well-being. Life extension work should not be an object of commerce, or profit, but a life saving activity of every well ordered health department. Enthusiasm and a knowledge of the appalling horrors of in-

dustrial disease, and not elaborate equipment, were needed to initiate this work.

Milk and the War.—Dr. Charles E. North of New York City said that it was desirable first to get a clear view of the position which the dairy industry occupied in the economic structure. The word "economics" had been to a large extent allowed no place in the deliberations of the American Public Health Association, or of health officers and sanitarians on the grounds that costs, prices, and profits and losses were commercial matters with which medicine and public health science had nothing in common. It happened, however, that the moment that public health authorities undertook to control the quality of a food commodity they immediately affected the quantity and the price. Consequently, any of the regulations or recommendations which might result from the activities of an organization such as the American Public Health Association and its section on Food and Drugs might affect not only the commercial structure of a great industry, but the quantity and the prices of a commodity offered to the consuming public. In 1917, according to figures obtained from the United States Department of Agriculture, there was produced in the United States over 84,000,000,000 pounds of milk; 43 per cent. was used as fluid milk, 41 per cent. as butter, 5 per cent. as cheese, 2.9 per cent. as condensed milk, 3.7 per cent. as ice cream, and 4.3 per cent. was fed to calves and pigs. The first effect of the war on the dairy industry was similar to its effect on the other food industries; namely, a great increase in the cost of raw materials and in the cost of labor. A tabulation of stable food commodities from July, 1910, to 1918 showed milk costing 21.2 cents per gallon in 1910 and 30.2 cents per gallon in 1918 with other foods showing a similar increase. One of the chief causes for this was the demand for export trade, and to these exports the dairy industry made some very large contributions, principally in butter, cheese, and condensed milk. Condensed milk shipments alone increased from 3,000,000 cases in 1915 to 25,129,000 in 1917. In considering the economics of the dairy industry one point of importance which was commonly overlooked and but little understood by the consuming public was the enormous fluctuations in supply and demand and the inequalities between these two factors. These fluctuations were so great that at certain seasons of the year at least 100 per cent. more milk was being produced than was being consumed, while at other seasons there was a shortage amounting to 25 per cent. Attempts were made to adjust these differences through the manufacture of surplus milk into by-products. When, however, all of the fluid product was paid for at the full fluid price and the manufacture of by-products entailed at times enormous financial losses, which could only be made up by an increased retail price of such fluid milk as was sold. The effect of the war on the milk producer had been to increase his two largest cost items; namely, the cost of grain and of labor. In 1914 the cost of producing 100 pounds of milk was $2.08, or 4½ cents per quart. In 1918 the cost was $3.60, or about 8 cents per quart. The effect of the war on the milk distributer had been to enlarge practically every cost item, including labor. In 1915 the cost of milk distribution was about 5 cents per quart, milk retailing at that time at 9 cents; in 1918 the cost of distribution was over 8 cents per quart, the same milk retailing at 17 cents per quart. These cost items had been carefully studied by the Federal Food Administration and were accepted by them as the basis for present payments to the producers and the retail prices to consumers. War conditions had greatly intensified the public interest in possible economies in the milk industry. There were many of these which could be instituted both in the departments of milk production and milk distribution. One of the most obvious was the elimination of milk wagons, and this applied to fully as great an extent to the country end of the line as to the city end. A survey of eleven large country milk shipping stations in New York State revealed the fact that 453 farmers' wagons were carrying milk to railways which could be easily carried by 44 wagons. In New York City there were 4,978 licensed retail wagons while the actual number needed to carry the retail milk was only 2,243. There were also 1,522 licensed wholesale wagons for milk which could be carried by only 300 wagons. The economies which would result from centralizing the delivery system of city wagons alone would amount to about one-half cent per quart. Other economies in distribution and in production might make it possible to reduce the total cost of milk as much as 2 cents per quart. Figures compiled by Professor H. C. Sherman of Columbia University seemed to fix the place occupied by milk in the United States as representing from 10 to 12 per cent. of the total cost of all food, while butter occupied a position between 5 and 9 per cent. of the cost of all food. As a result of the war while the cost of eggs had increased 269 per cent. and beef 166 per cent., the cost of milk even at 17 cents per quart had increased only 88 per cent. It was his opinion that the poor and the infants in our large cities were not suffering so much from the high prices of milk as they were from ignorance of the real value of milk as compared with other foods.

Registration of Births and Deaths in Illinois.—Dr. C. St. Clair Drake of Springfield, Ill., stated that, while a law requiring reports of births and deaths was enacted in Illinois in 1877, in the fifty-ninth year of statehood, it was not until almost forty years later that a good law affecting vital statistics was secured, and it was not until the year that marked the State centennial anniversary that Illinois was recognized as a registration State by the United States Bureau of the Census. The interim of forty years, between the passage of the law of 1877 and that of 1915, was marked by many appeals to the General Assembly for a satisfactory law, each attempt being met with a certain amount of opposition, based to a large extent upon lack of education as to the acute need for such a law and to the geographical conditions and differences in the origin and distribution of the population. The law which was finally secured in 1915 was patterned largely after the so-called model law. It divided the State into very small and convenient districts for registration purposes, designating the duly elected officials of these districts as registrars and making registration a duty similar to any other prescribed by law pertaining to official position. Public officials of this type were in all instances permanent residents of their communities, usually fully conversant with local happenings and capable of knowing, through common report, the extent to which the law was being ignored or violated. While the law afforded every reasonable convenience to the public, it did away with the fees that were paid under the old law and, for this and for other reasons, it was obvious that its successful application would necessitate a broad campaign of education to supplement the legislative enactment. From the moment that the law was passed, this educational campaign had been carried out. The press service and other means of publicity of the Division of Public Health Instruction were employed, motion pictures were prepared and sent out through the State, and portable exhibits shown at fairs, conventions and public gatherings, held firmly before the people that vital statistics must be regarded as the very foundation of any constructive public health work. The people were impressed in every way with the discredit associated with the previous failure on the part of Illinois to do her part in this direction. While the registration districts were very small and the registrars officials generally well known, the difficulty of not knowing the proper person to whom to apply had been largely overcome by the publication of a complete State register of registrars, which had been sent to all physicians, undertakers, and other interested persons. It might be stated in this connection, that the undertakers upon whom the burden of carrying out the details of the law were imposed, and who, incidentally, were loud in their protests against the law in 1901, had met the requirements of the present act cheerfully and with general uniformity. The law became effective July 1, 1915, and steps were taken at once to place it in operation by the State Board of Health. The next General Assembly enacted the Civil Administrative Code, entirely reorganizing the State government of Illinois, through which the functions of the State Board of Health were taken over by the State Department of Health. It was not until 1917, when this general change came, that the vital statistics machinery of the State was fully organized, so in practical application the new law was put in definite operation by the newly

created department. During the autumn of the present year, after due investigation, Illinois was recognized as a registration State by the United States Bureau of the Census, the mortuary returns being found to be something over 93 per cent. complete. The birth returns, of course, had not proven so satisfactory, and the department was continuing in developing its educational work to increase birth registration. To this end a survey was undertaken by the State Federation of the Women's Club and the department in which every available means of education was employed, and a further broad campaign was launched in conjunction with the Women's Council of National Defense in Illinois, as a part of the program for Children's Year. As a means of encouraging registration on the part of parents, the department had prepared an engraved certificate of registration which was sent without charge and accompanied by educational material on the care of the child to the parent of every infant duly registered in Illinois. The increase in birth returns was steady and in the main satisfactory. For the first time in the history of the State it was now possible to utilize the existing mortuary figures to estimate, with a reasonable degree of certainty, the prevalence of communicable diseases and the cost of these diseases to the people of the State. Based upon these mortuary figures and checked up as far as possible by morbidity returns, there had been prepared in the office of the department a table which indicated that eleven principal preventable diseases had occasioned the State of Illinois during a single year a total loss of $154,881,685. However accurate or inaccurate these estimates might be, Illinois for the first time in its history was able to utilize her mortuary statistics for public health purposes with the assurance that these mortuary figures were something over 90 per cent. complete. Under the provisions of the present law, with certain minor amendments which might prove advisable, and with the great impetus which the present war had given to birth registration, and the ever growing interest on the part of the people in public health affairs, it was believed that it would not be long before Illinois could qualify as a registration State in births as well as deaths and thereby make an end to the many years of relative neglect and inactivity of the practical features of birth and death bookkeeping.

Report of Committee on Closing Schools as a Means of Controlling Epidemics.—Mr. WILLARD S. SMALL, Chairman of the Bureau of Education, stated the following resolution was adopted by the American Public Health Association, October 20, 1917: "RESOLVED, That it is the sense of the American Public Health Association that the Federal Bureau of Education should attempt to discover what is proper practice as to continuing or closing the schools as a means of controlling epidemics of measles, whooping cough, scarlet fever, diphtheria, smallpox, and poliomyelitis, and that they should publish their conclusions in the annual report of the Bureau and in bulletin forms." This service was accepted by the Bureau of Education upon the condition that a committee of the association be appointed to cooperate with it in carrying out the purposes of the resolution. The committee believed the facts and conclusions as presented in this preliminary report were correct and sound, and that the final report would merely amplify and confirm these facts and conclusions. An inquiry consisting of fourteen questions was sent to fifty cities in thirty-one States. Replies were received from thirty-two cities in nineteen States.

Conclusions: "(1) Closure of schools as a means of controlling epidemics of the six diseases specified is unnecessary, unscientific, and unjustifiable. (2) Disinfection by fumigation is unnecessary and ineffective. The use of chemical solutions is generally unnecessary. Disinfection by air and sun and cleansing with hot water, soap, and scrubbing is to be commended. (3) The proper method of control involves sufficient inspectorial force of physicians and nurses to maintain close supervision of cases and contacts; enforcement of isolation and quarantine under elastic administrative regulations; the employment of clinical and laboratory tests and reliance upon such data; close correlation of the school medical inspection, on the one hand, with the health department, and, on the other hand, with the school forces; and continuous education of the public. (4) The wide diversities in rule and practice revealed by this study should be eliminated or reduced. It is unreasonable, unscientific, and absurd that there should be such variations in the minimum period of exclusion as from fourteen to forty-two days (scarlet fever). This is merely typical of many variations that could and should be eliminated. They do not depend upon adequate or inadequate support of medical inspection; they depend solely upon ignorance, indifference or unreasonable difference of opinion. Much of this diversity would be eliminated by acceptance by all school health officers of the standards set up in the report of the Committee on Standard Regulations for Control of Communicable Diseases, submitted to and adopted at the last meeting of the American Public Health Association."

Recommendations: (1) That this preliminary report be approved and adopted by the American Public Health Association. (2) That the committee be continued and requested to complete its work and amplify the report by inclusion of specific citations of rules and practice. (3) That the committee be requested to confer with the Committee on Standard Regulations for Control of Communicable Diseases with a view to summarizing the standards of this committee in so far as they apply to the control of communicable diseases in schools and adapting them to the specific problems of schools. (4) That the American Public Health Association authorize the committee to arrange with the Bureau of Education to publish and distribute the report as soon as completed.

One Year of Infant Mortality in the United States During War.—Mr. FREDERICK S. CRUM stated that the influenza epidemic had already resulted in a large infant mortality. The effect of the epidemic was seen clearly in the 46 individual cities which reported weekly to the United States Bureau of the Census and, of course, it was equally apparent in the infant deaths and death rates by geographical groups of cities. Even in the North Atlantic cities, which include Boston, the effect of the epidemic was not reflected in the infant mortality rate prior to the week ending September 14. By October 1 the epidemic was clearly reflected in the infant death rates of several of the cities in the North Atlantic group. Comparing the infant mortality during the nine weeks ending November 30, 1918, and the nine weeks ending December 1, 1917, they found that it was 70 per cent. higher in 1918 in the north Atlantic cities; 72 per cent. higher in the central Atlantic cities; 61 per cent. higher in the Southern cities; 33 per cent. higher in the cities of the middle west; and 41 per cent. higher in the western cities. Through the various intensive studies of infant mortality by localities many interesting and valuable facts relating to the fundamental or underlying causes of infant mortality were being learned. Equally valuable were the studies which were being made by the various child hygiene bureaus, departments or divisions of our State and municipal departments of health. The Cincinnati unit organization also represented one of several special activities which were throwing new light upon the complex problems of infant mortality. The experience in England, France, Germany, New Zealand, the United States, and elsewhere seemed to prove quite conclusively that the most immediately hopeful method of attack upon infant mortality was through education of the mother and more particularly in how properly to care for herself before and after the birth of the child and in the great importance that attached to breast feeding of the infant. In New Zealand, where these methods had perhaps been carried farthest under the auspices of the Royal New Zealand Society for the Health of Women and Children, cooperating with the government, the infant deaths for the year 1917 were only 48.2 per 1,000 of living births. The war seemed to have had little effect upon the infant death rate in New Zealand, whereas in the United States, already existent child-conservation organizations were active in keeping up the public interest in the work.

Beneficial Consequences of Food Shortage in Germany.—Among the diseases favorably influenced by underfeeding are appendicitis, eclampsia, diabetes, rheumatism and gout. Laborers suffer under the regimen and neurasthenics abound.—*La Presse Médicale.*

Philadelphia Neurological Society.

At a stated meeting held December 18 Dr. Nathan S. Yawger exhibited "A Case of Syphilis Hereditaria Tarda, with 'Tiptoe Gait.'" The patient was a girl, ten years old, who was apparently well until the age of six, when she began to exhibit signs of mental deterioration, which progressed to a state of imbecility. At the same time she developed the peculiarity of walking and running on the tips of her toes, much as a ballet dancer. The knees became overextended in action, but x-ray examination failed to disclose anatomical changes in the joints. The muscles of both upper and lower extremities were well developed. The reflexes were slightly increased, but there was no spasticity, no ankle-clonus, and no Babinski reflex. The teeth were of the Hutchinson type, pegged, notched, distorted. There was a scar on the cornea. The blood yielded a negative Wassermann reaction. Spinal fluid could not be obtained. The father admitted having had gonorrhea, but denied luetic infection, and his blood also yielded a negative Wassermann reaction.

Dr. Thomas E. Shea exhibited by invitation "A Case of Median-Nerve Injury Due to Stab-wound from the Ulnar Side of the Hand." The patient was a young man who was stabbed with a pocket knife through the hypothenar eminence. At once the hand became numb, and power was lost in the thumb and index and middle fingers, with loss of sensibility and muscular wasting. A trophic ulcer formed on one of the affected fingers and a slight burn caused desquamation of the skin covering a portion of the affected parts. Under treatment with electricity and massage improvement set in, and in view of the circumstances surgical intervention seemed at this time not indicated. The conclusion was reached that the median nerve, and especially its superficial fibers, had been close to its point of division for the supply of the outer portion of the hand and the thumb and the index and middle fingers.

Dr. Francis X. Dercum exhibited "A Case of Hysteria with Multiple Operations." The patient was a woman of neurotic temperament who had been subjected to five successive abdominal operations for the relief of pain referred to different viscera, but without relief. The patient winced when a fold of the skin was pinched, but she bore pressure in the same situation without apparent discomfort. Dr. Dercum imagined cases of the same kind must come more or less frequently under observation of neurologists and he cautioned against operations in neurotics in the absence of positive indications. On the other hand, care must be taken not to neglect necessary operation in an individual who happens to be neurotic.

Dr. Dercum exhibited also "Two Cases of Friedreich's Ataxia in Brothers." The patients were children, six and eight years old respectively, born of an alcoholic father, and who presented ataxic gait, with loss of knee-jerk on one side and diminution on the other, with perhaps slight mental deficiency.

Dr. Sherman F. Gilpin exhibited "A Case of Tabes Dorsalis Showing Results of Treatment, Including Drainage of Cerebrospinal Fluid." The patient was a woman with classical symptoms in whom the Wassermann reaction became negative and the number of cells in the spinal fluid diminished, while gait and station were much improved. The treatment consisted of frequent inunction with mercurial ointment, together with as complete evacuation as possible of cerebrospinal fluid about once a week or two weeks. The case was one of a considerable number of tabes, taboparesis, and paresis treated in the same way, as a rule with distinct advantage and without any untoward result whatever. It was suggested that the improvement might be due to relief of pressure, with a resultant good effect on the nutrition of the cord, the possible induction of passive hyperemia, and the elimination of toxic substances.

Dr. Alfred Gordon exhibited "A Case of Nystagmus on Monocular Vision." The patient was a girl, fifteen years old, who presented some fullness of the neck perhaps referable to the thyroid gland, slight protrusion of the eyes and some acceleration of pulse. It was noted that, while the eyes could be rotated laterally in association, when one eye was covered nystagmus developed in the exposed eye. It was suggested that the condition was due to weakness of the external recti.

Dr. James Hendrie Lloyd read for Dr. Charles K. Mills "A Biographical Sketch and Appreciation of Major Alfred Reginald Allen, U. S. A., who died of gunshot injuries in September, 1918, while leading his battalion at the battle of the Meuse. Dr. Allen had been at different times President and Secretary of the Society, Secretary-Treasurer of the American Neurological Association, President of the American Psychopathological Association, and Associate in Neuropathology in the University of Pennsylvania.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Dominion Medical Examining Boabd.

Toronto, June, 1918.

(*Concluded from page* 46.)

MEDICINE (including THERAPEUTICS).

1. Hematuria: Give the causes. Where it occurs in tuberculosis of the kidney give the other symptoms and signs of the onset and course of this lesion which justify the diagnosis.

2. Edema: Give your conception of the causes producing edema. Describe the signs and symptoms of edema of the lungs and give the treatment.

3. Describe the signs and symptoms which would lead you to suspect hyperthyroidism occurring alone or complicating other diseases.

4. Give an account of the gastrointestinal symptoms which may be produced by cholelithiasis without gallstone colic.

5. Give the causes of irregularities in the action of the heart, and describe how any one type of irregularity may be recognized clinically with or without instrumental records.

6. Discuss Allen's starvation treatment of diabetes with special reference to treatment of (*a*) obese individuals, (*b*) children, (*c*) chronic diabetes in emaciated men above middle-age.

SURGERY.

1. Describe the injury known as Colles' fracture, and write fully your treatment from the time of injury until discharged from your care. Discuss the occurrence of ischemic paralysis in this condition.

2. Mention the conditions that cause pain in the right lower quadrant of the abdomen, male and female, and discuss the differential diagnosis of each.

3. Enumerate the various forms of goiter. Discuss the medical and surgical treatment of exophthalmic goiter.

4. What are the different causes of pyuria? How would you determine the source of the pus? Describe the symptoms and physical signs of a case of tuberculosis of the kidney, with treatment.

5. A machine gun bullet enters one inch below the right nipple and leaves the chest at the inferior angle of the right scapula. Describe (*a*) immediate symptoms and signs; (*b*) immediate treatment; (*c*) complications and their treatment.

6. Discuss the differential diagnosis of carcinoma of the breast. Describe the operation you would perform.

PATHOLOGY AND BACTERIOLOGY.

1. (*a*) Describe in detail your method of isolating the micro-organism in the blood in a case of streptococcus septicemia. (*b*) How would you prepare a vaccine after you have isolated the bacterium?

2. What are the pathological changes occurring in the lung in acute lobar pneumonia? Describe macroscopically and microscopically the various stages.

3. Describe fully the blood picture in a case of myelogenous leukemia. What changes would be found in the internal organs?

4. (*a*) Discuss the relationship between the human and bovine types of tuberculosis. (*b*) What is the Von Pirquet test, how is it applied, and what is its significance?

5. Describe the principle of complement-fixation and discuss the importance of the Wassermann test in the diagnosis of syphilis.

6. Classify tumors of the breast. Describe the gross and histological features of one benign and one malignant tumor of this region.

ANSWERS.

MEDICINE (including THERAPEUTICS).

1. *Causes of hematuria:* Acute nephritis, acute congestion of the kidney, chronic nephritis, severe forms of acute infectious diseases (as scarlet fever), hemophilia, scurvy, purpura, filariasis, tuberculosis of kidney, cancer of kidney, poisoning by turpentine or phenol or cantharides, calculus, ulcer or cancer of the bladder, traumatism or disease in the urethra.

In *tuberculosis of the kidney* there is pain over one or both kidneys, frequency of urination, the urine is acid and contains pus, blood, albumin, and tubercle bacilli; chills, sweats, fever, and emaciation may follow in severe cases.

The diagnosis is made by finding the tubercle bacilli in the urine, and then by culture and inoculation into guinea pigs; ureteral catheterization shows which kidney is involved. Frequently *x*-ray examination will show calcareous or caseous foci in the kidney. General symptoms are hectic fever, tuberculosis in lungs (and elsewhere), malnutrition.

2. *Edema may be caused* by: "(1) Differences of pressure, a filtration process. (2) An increased secretion by the endothelial cells of the vessels. (3) Osmosis, resulting from variations in the relative concentration of salts, particularly sodium chloride, on either side of the osmotic membranes, the cell walls. (4) The most satisfactory explanation of the occurrence of edema can probably be based upon the properties of colloidal (non-crystalloid) bodies such as gelatin and, presumably, other proteins. If dried gelatin is placed in water, it will absorb a definite quantity of that water and will swell up to a certain point. If the water be slightly acidified the amount absorbed becomes very much greater. It has been shown that an inadequate supply of oxygen results in the production in the tissues of acids, particularly lactic acid and carbon dioxide, which, in turn, increase the tendency of colloids to take up water; consequently edema is brought about. There is probably little of it due to increased capillary pressure or to secretory activity on the part of the endothelium of the blood-vessels."—(McConnell's *Manual of Pathology.*)

EDEMA OF THE LUNGS.—"The symptoms consist in rapidly developing dyspnea, cough, and expectoration. Breathing is very difficult and becomes progressively worse as the exudate continues to accumulate. The patient is anxious and terrified and is fully conscious of the danger which threatens him. As the edema increases the pulse becomes weak and small, cyanosis changes to lividity, a cold sweat breaks out over the body, the extremities become icy, consciousness is lost, and death ensues under all the manifestations of profound asthenia. The temperature is usually subnormal. . . . The physical signs are not characteristic. Upon percussion normal resonance is found to be diminished, particularly over the posterior portion of the lungs. Occasionally small patches of tympany may be found interspersed throughout the dull area. Upon auscultation various rales—fine and coarse, mucous, bubbling, and crepitant—are heard."

"*Treatment* must be directed both to the immediate source of danger to life—that is, to the edema—and to the causative affection. For the first purpose, counter-irritation in the form of dry cups or a large mustard plaster should always be employed, and in the more urgent cases venesection may be used with advantage. When cups are used they should be placed over the entire posterior pulmonary area. Inhalations of oxygen may be tried in the hope that they will allay dyspnea. The heart must be stimulated by camphor and ether administered hypodermically. A solution containing one grain of camphor to ten minims of ether is well adapted for ordinary use; ten minims of this solution may be injected beneath the skin every half-hour. Atropine is another drug of value; give 1/50 of a grain hypodermically for the first dose and then use a smaller quantity at the end of three hours if indications for its employment are still present."—(From Osler and McCrae's *Modern Medicine.*)

3. The *clinical evidence of hyperthyroidism* is thus summed up by Schäfer: Rapid and often irregular pulse; nervous and psychical excitation, with muscular tremors; a feeling of warmth in the skin, and throbbing of cutaneous vessels, often accompanied by profuse sweating; shallow respiration; markedly increased metabolism (especially nitrogenous), with abnormal appetite and loss of body fat; a decreased assimilatory power for carbohydrates; an anxious, restless expression; prominence of the eyeballs; wide palpebral aperture, often with dilatation of pupils. The enlargement of the thyroid may involve only one lobe.

4. *The gastrointestinal symptoms which may be produced by cholelithiasis without gallstone colic* are chronic, long-continued, or recurring indigestion; often there are no symptoms for a time, later there will be observed the "inaugural symptoms," described by Moynihan as follows: "The patient complains of a fullness, weight and distention or oppression in the epigastrium coming on soon after meals, within half or three-quarters of an hour, relieved by belching and dismissed almost on the instant by vomiting, elicited with remarkable constancy by certain articles of diet, especially those of a greasy nature and depending rather on the quality than on the quantity of the food. There is a sensation of great tightness which if unrelieved may become acute pain from which the patient obtains ease by bending the body forward, by flexing the right thigh on the abdomen, or by loosening all garments which fit tightly to the waist. There is frequently great complaint of acidity or heartburn, and in the act of belching there may be sour or acid regurgitation. While the discomfort lasts the patient may notice a catch in his breath and he finds, perhaps, that it is impossible to breathe deeply without feeling an acute stabbing pain at the right costal margin. There may be a feeling of faintness and nausea, and, rarely, vomiting may occur spontaneously. After a more than usually severe attack of indigestion the body and side may feel stiff for several days. A frequent and characteristic early symptom is the occurrence, during an attack of indigestion, of a slight sensation of chilliness, especially in the evenings after a meal. The sensation of goose-flesh is often experienced."

5. *Causes of palpitation of the heart:* "Among the more important causes may be mentioned female sex, puberty, menstrual disorders, anemia, emotion, mental anxiety, hysteria, overexertion following acute or chronic disease, 'heart-strain' (Da Costa), dyspepsia, long-continued use of tea, coffee, tobacco, and alcohol in large quantities, and excessive venery."

Causes of Tachycardia: "The direct cause is somewhat obscure. The condition may be found associated with one of the crises of cerebral or spinal disease, the menopause, neuritis of the pneumogastric nerve, chronic myocarditis, neurasthenia, chronic gastritis, the excessive use of tobacco, petit mal, pyrexia, lesions of the base of the brain, etc."

Causes of Bradycardia: "It is often associated with organic nervous diseases and is a symptom of such cardiac diseases as fibroid and fatty heart and atheroma of the coronary arteries. The condition frequently occurs during convalescence from infectious diseases, such as diphtheria, pneumonia, typhoid fever, erysipelas, and rheumatism; uremia, lead-poisoning, anemia, and chronic alcoholism are often causes. According to Balfour, "Many, if not most, of the sufferers from bradycardia are epileptics."

Causes of Arrhythmia: "Valvular diseases; myocardial diseases; cardiac dilated hypertrophy; atheroma of coronary arteries and aorta; excessive use of tobacco, tea, or coffee; flatulent dyspepsia; neurasthenia, hysteria, and melancholia."

Usually *palpitation of the heart* has a sudden onset after some one of the causes mentioned, with precordial oppression or pain; rapid, tumultuous beating, the impulse being visible through the patient's clothing; dyspnea, anxiety, and a sense of choking or fullness in the throat, the recumbent position being impossible; vertigo, faintness, flashes of light, the pulse full and strong or feeble, and the face flushed or pale, the patient having a feeling of anxiety with a sense of impending danger and a fear of sudden death. These

attacks are paroxysmal, lasting from a few moments to several hours or a day, the patient often voiding a large quantity of limpid urine after the paroxysm has subsided, when there is a strong tendency to sleep. Irritability of the heart is differentiated from the various forms of cardiac disease by the absence of all the physical signs occurring in those conditions."—(Hughes' *Practice of Medicine.*)

6. *Allen's starvation treatment in diabetes.* The essential part of this treatment is complete rest of the alimentary tract so long as even a trace of sugar is found in the urine. The patient is, first of all, starved until his urine is free from sugar and for a further period of twenty-four hours. During this period water, tea, and coffee may be taken. The carbohydrate tolerance is then ascertained. The next step is the arrangement of a scheme for diet, in which the *intake* of *proteins*, of *fats*, and of *carbohydrates*, and the *bulk of the food* have each to be determined. It is impossible to lay down hard and fast rules; each case must be considered separately, and the treatment made as *individual* as possible.

The following outline of this method of treatment has been prepared by Dr. Joslin and is issued by him to his patients: *Fasting*—Fast until sugar-free. Drink water freely and tea, coffee and clear meat broth as desired. In very severe, long-standing and complicated cases, without otherwise changing habits or diet, omit fat, after two days omit protein and halve carbohydrate daily to 10 gm., then fast. *Alcohol*—If acidosis (diacetic acid) is present, take 0.5 c.c. alcohol per kilogram body weight daily until acidosis disappears. Alcohol is best given in small doses every three hours. *Carbohydrate Tolerance*—When the twenty-four hour urine is sugar-free, add 150 gm. of 5 per cent. vegetables, and continue to add 5 gm. carbohydrates daily up to 20, and then 5 gm. every other day, passing successively upward through the 5, 10, and 15 per cent. vegetables, 5 and 10 per cent, fruits, potato and oatmeal to bread, unless sugar appears or the tolerance reaches 3 gm. carbohydrate per kilogram body weight. *Protein Tolerance*—When the urine has been sugar-free for two days, add 20 gm. protein (3 eggs) and thereafter 15 gm. protein daily in the form of meat until the patient is receiving 1 gm. protein per kilogram body weight, or if the carbohydrate tolerance is zero, only ¾ gm. per kilogram body weight. *Fat Tolerance*—While testing the protein tolerance, a small quantity of fat is included in the eggs and meat given. Add no more fat until the protein reaches 1 gm. per kilogram (unless the protein tolerance is below this figure), but then add 25 gm. daily until the patient ceases to lose weight or receives not over 40 calories per kilogram body weight. *Reappearance of Sugar*—The return of sugar demands fasting for twenty-four hours or until sugar-free. The diet is then increased twice as rapidly as before, but the carbohydrate should not exceed half the former tolerance until the urine has been sugar-free for two weeks, and it should not then be increased more than 5 gm. per week. *Weekly Fast Days*—Whenever the tolerance is less than 20 gm. carbohydrate, fasting should be practised one day in seven; when the tolerance is between 20 and 50 gm. carbohydrates, upon the weekly fast day 5 per cent. vegetables and one-half the usual quantity of protein and fat are allowed; when the tolerance is between 50 and 100 gm. carbohydrate, the 10 and 15 per cent. vegetables are added as well. If the tolerance is more than 100 gm. carbohydrate, upon weekly fast days the carbohydrate should be halved.

In *obese individuals* extra caution is necessary in reducing the body weight.

In *children* the prognosis is poor, but the diet is borne well and should be rigidly adhered to. The physician must remember not to increase the amount of carbohydrates, etc., as if he were prescribing for an adult, but the weight of the child must be observed. Children are especially sensitive to acid poisoning.

In *emaciated chronics above middle age* changes in diet and régime are dangerous; these patients must be watched very carefully, and acidosis should be avoided.

SURGERY.

1. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backwards and upwards, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture.

Treatment.—"It cannot be too strongly insisted upon that success in the treatment of Colles' fracture with displacement depends chiefly upon complete and accurate reduction, and to enable this to be effected a general anesthetic is of great assistance, especially when impaction exists. The surgeon grasps the patient's hand, as if shaking hands with him, and, resting the palmar surface of the wrist on his bent knee, makes traction through the hand, and counter-extension through the forearm, with lateral movements, if necessary, to undo impaction. When the fragments are freed from one another, the wrist is flexed, and the hand carried to the ulnar side, while the fragments are moulded into position. When reduction is complete, the deformity almost entirely disappears, and the two styloid processes regain their normal positions relative to one another. As there is no tendency to redisplacement, no retentive apparatus is required, but, as it adds to the patient's comfort and sense of security, a firm flannel bandage, a broad strip of adhesive plaster, or a poroplastic wristlet may be applied. In severe cases, however, anterior and posterior splints, similar to those used for fracture of both bones of the forearm, or a dorsal splint padded so as to flex the wrist to an angle of 45°, but somewhat narrower, may be employed. The hand and forearm are in any case supported in a sling. To avoid the stiffness which often follows this fracture, the massage and gentle movement of the wrist and fingers should be carried out from the first, the range of movement being gradually increased until the function of the joints is perfectly restored. If splints are used, they should be discarded in a week, and the patient is then encouraged to use the wrist freely."—Thomson and Miles' *Manual of Surgery.*)

Ischemic paralysis is a degeneration of the tissues of the limb (chiefly of the muscles) and is due to arrested blood supply caused by tight bandaging; sometimes the nerve is also damaged. It has been observed even when splints are not employed. There is muscular degeneration, followed by fatty infiltration, induration, and contraction; the conditions may come on rapidly. The prognosis of this condition is not very good. It mild cases, massage, electricity, and attempts to straighten the fingers may prove of service. In severe cases the muscle tendons have been lengthened; shortening of the bones has also been tried.

2. Conditions that cause pain in the right lower quadrant of the abdomen are: Appendicitis, uterine or ovarian disease, pelvic inflammations, ectopic gestation, peritonitis.

In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

In *inflammation of the right ovary* the pain is not localized, but may be bilateral, and spreads to the vagina and rectum; there is no tenderness at McBurney's point; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

In *salpingitis* there is a dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis;

sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesion; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain.

Pelvic peritonitis is characterized by: Intense and diffuse abdominal pain, tenderness, and distention; vomiting, constipation, elevation of the temperature (103°-104° F.), small, hard, rapid, and wiry pulse (120-140), and increased respiration (30-40) of a painful character are also present. The dorsal decubitus with the legs and thighs drawn up is assumed.

For *ectopic gestation* see OBSTETRICS AND GYNECOLOGY, Question 3.

3. The *various forms of goiter* are: (1) Exophthalmic; (2) simple or parenchymatous; (3) cystic; (4) fibro-adenomatous; (5) acute, and (6) malignant.

Medical treatment includes rest (both physical and mental), hydrotherapy, proper diet (avoiding too much food, also indigestible and stimulating food), and fresh air. Medicine should be given only when indicated for symptoms; strychnine, atropine, bromides, hypnotics, digitalis, strophanthus, iodides, cathartics, etc., have all been used; electricity, suggestion, *x*-rays, and organotherapy have also been advocated.

Surgical treatment: The whole gland must not be removed, or myxedema may result; and the parathyroids must not be removed, or the patient may develop tetany. Ligation of one or more of the thyroid vessels may be done, or one-half of the gland may be removed. Local anesthesia is safer than general anesthesia in these cases.

In some cases the disease tends to spontaneous recovery. Probably the surgical treatment affords the best chance of cure or alleviation of symptoms. But before operation the patient should have complete rest, both bodily and mental, and during this time the various medical measures mentioned may be tried.

4. *Causes of pyuria:* Infection in the kidney (including tuberculosis), abscess, nephrolithiasis, pyelitis; ureteritis; cystitis; urethritis. To determine the source of the pus:—The patient should pass his urine into three separate vessels; if the urine in all three is similarly affected, the pus is from the kidneys; if most of it is in the first vessel, the pus is from the urethra; if most of it is in the last vessel, the pus comes from the bladder.

In addition, the use of the cystoscope, and catheterization of the ureters may enable one to see the source of the pus.

Signs and symptoms of tuberculosis of the kidney: Pain—Slight at first; severe later; attacks of colic from blocked ureter; some tenderness on palpation. *Tumor*—Moderate size, often due to perinephritis; ballottement well marked; may be lobulated. *Urine*—Polyuria; acid; pyuria and hematuria; urea and phosphates diminished; great variations due to blocking ureter. *Pyuria*—Dirty grey pus in small quantity; mixed with caseous masses and phosphatic débris. *Hematuria*—Very constant symptom; slight in amount; sometimes clots moulded in ureter. *Bacilli*—Tubercle bacilli in small numbers and difficult of detection. Septic organisms become abundant late in the disease. Absence of other organisms in acid purulent urine points to tubercle. *Cystoscopy*—Ureteral orifice is red, with pouting, swollen lips, or retracted. Methylene blue given as a hypodermic is not excreted, or excreted very slowly, by the diseased kidney. *Per rectum or vaginam*—The thickened ureter may sometimes be felt. *Albuminuria*—Always present when pelvis is diseased. *Polyuria*—Very marked, especially at night. *Dysuria*—Pain in neck of bladder. The earliest symptoms. Sometimes due to phosphatic débris in bladder. *Constitutional*—Evening temperature raised to 100°-101° F.; if secondary sepsis has occurred, to 103°-104° F. Loss of flesh. Anemia. Rigors and sweats in last stage.—(Grove's *Synopsis of Surgery.*)

Treatment: If on exposure of the kidney a limited portion is found to be diseased, a wedge-shaped portion is excised. If, as is more usual, the kidney is extensively affected, two methods may be adopted: (1) If the other kidney is healthy, nephrectomy with removal of as much of the ureter as possible is done. (2) Nephrotomy, followed by drainage, is done when the patient's condition is too bad to stand the bigger operation, or when the other kidney is also affected.

5. The *immediate symptoms and signs* will be shock, pain (sometimes comparatively slight), dyspnea, hemoptysis, vomiting, and hiccough. *Immediate treatment* should include as much rest as possible, a hypodermic of morphine (¾ to 1 grain) with atropine sulphate, plenty of fluid to drink (but not alcohol), and aseptic pads applied to the wounds. The patient should be moved as little as possible.

Later complications include injury to the chest wall, surgical emphysema, hemothorax, pyothorax, pneumothorax, and injury to the lung.

For the *hemothorax* rest in bed is necessary; do not explore unless infection is present; potassium iodide in 15-grain doses may be given t.i.d. for three days; tincture of iodine may be used as a counterirritant; the wounds of entrance and exit of the bullet should be cleansed. For *pyothorax* excision of one or two ribs may be necessary. (From J. Keogh Murphy's *Wounds of the Thorax in War.*) The same writer gives the following summary: (1) Modern bullet wounds of the thorax usually keep a straight course along the line the bullet has entered the thorax. (2) The entrance and exit wounds are usually much the same in size. An expansive exit wound is uncommon, unless the bullet strikes the spine or the shoulder. (3) The wound is probably uniformly septic from end to end, but this sepsis is of a mild character and in the deeper parts is usually overcome by the body itself. (4) The danger of probing bullet wounds of the thorax is extreme and real. (5) Bullets usually lodge in the posterior part of the thorax. If they become subcutaneous they can readily be removed, but otherwise they should be left alone. (6) Comminuted fracture of the ribs is usually very septic. (7) An uncomplicated hemothorax should be left alone. (8) It is by no means uncommon for a hemothorax to become infected, especially where there has been much movement of the patient, and such cases should be dealt with and given the proper drainage. (9) A localized pneumothorax is not uncommon. (10) The immediate treatment of wounds of the thorax differs considerably from the treatment which should be adopted at a later stage. (11) The employment of bacterial therapeutics should never be neglected, for, even if the results are sometimes disappointing, no harm to the patient can ensue."

6. The two breasts should be inspected, and any abnormal appearance should be noted. Then the physician, standing behind the patient, should palpate the breast, noting the location of the lump, its size, shape, and consistence; this should be done by making firm pressure with the flat of the hand. Then the condition of the skin should be observed, to see if there is any abnormal attachment to the breast or tumor; note if the nipple is retracted; observe also if the breast is freely movable on the chest wall. The condition of the lymphatic glands in the axilla and above the clavicle should be observed. The main object of the diagnosis is to differentiate between a benign and a malignant tumor. In well-marked cases this is not difficult. *Benign tumors* grow slowly and gradually; as a rule, they are freely movable, firm, round, and the nearer they are to the skin the softer they are; they are not encapsulated, and do not cause retraction of the nipple or enlargement of the neighboring lymphatic glands. *Malignant tumors* grow rapidly, are movable in the early stages, but later become adherent to the skin or pectoralis major muscle; they are hard and immovable; the nipple is retracted, and the axillary lymphatic glands are enlarged; pain is a symptom; cachexia may be noticed, and there may be metastatic growths. But there is a large group of *doubtful cases*, which can only be diagnosed by a microscopical examination of a piece of the tumor.

The patient should be advised, if the tumor is *malignant* (and it is not an inoperable case), that prompt thorough operation is absolutely necessary. If the tumor is *benign*, the tumor alone should be excised. In *doubtful* cases it is well to imagine the growth malignant until it is proved to be otherwise. If the breast is removed and the tumor is proved benign, the woman

has lost a breast; whereas, if it is not removed, and the tumor should prove to be malignant, she will lose her life. The best plan is (with the consent of the patient) to prepare for a radical operation, excise a piece of the tumor, have it examined microscopically, and if it proves to be benign, remove the tumor; if it is malignant, remove the whole breast and neighboring lymphatic glands.

The following table (from Eisendrath's *Surgical Diagnosis*) may prove useful:

	Chronic Cystic Mastitis.	Fibroadenoma.	Carcinoma.
Age	Usually before forty, but may occur before menopause, often more painful and larger during menses.	In young women.	Generally over forty, rarely before that age; accompanied by cachexia.
Location and growth	Multiple nodules in one or both breasts. Very slow growth, except in large cysts.	Anywhere. Grow very slowly.	Usually in inner quadrants. Grow rapidly.
Mobility	Not movable in breast unless one or more large cysts—then only moderate mobility.	Freely movable.	Movable in very earliest stage; later adherent to skin or pectoral muscle and fixed in breast.
Consistency and form	Large cysts either are round or fluctuate or are elastic. Smaller multiple nodules feel like beans.	Not as hard as carcinoma; outline rounded and sharp.	Very hard, irregular, and not demarcated.
Condition of nipple, and pain	Very rarely retracted. Tumors often painful, especially at menses.	No change. No pain, as a rule.	Early retraction. Often pain, quite severe and early.
Condition of axillary lymphnodes and metastases	Earlier enlargement than in cancer. Tender and soft. Often more painful during menses.	Not enlarged, as a rule.	Early enlargement. Induration very marked. Evidence of metastases.

"*Halsted's operation* aims to remove in one piece the entire breast and overlying skin, the costal portion of the pectoralis major, the pectoralis minor, and all the fat and glands of the axilla. The supraclavicular glands are removed in a second piece. An incision is carried through the skin and fat, and a triangular flap turned back. The costal portion of the pectoralis major is divided close to the ribs and separated from the clavicular portion, which with the overlying skin is divided up to the clavicle, exposing the apex of the axilla; these flaps are drawn upward with a retractor and separated from the underlying tissues, and the muscle further split as far as the humerus, where it is severed close to the bone. The breast, pectoralis major, and all fat are stripped from the chest wall, including the pectoralis minor, which is divided at each end, thus exposing the entire axilla, which is cleansed of fat and lymphatic glands from above and within, downward and outward, all small vessels being ligated close to the axillary vessels, which, with the nerves, should alone remain. The triangular flap of skin is drawn outward and the lateral and posterior walls of the axilla likewise cleared, the subscapular vessels being ligated, and the subscapular nerves preserved if possible. The mass is then turned inward and removed from the chest. A vertical incision is now made along the posterior margin of the sternomastoid, and the supra- and infraclavicular fat and glands removed by dissecting from the junction of the internal jugular and subclavian veins downward and outward. The cervical wound is sutured, and the edges of the chest wound approximated by a buried purse-string suture of silk, which includes the base of the triangular flap, the apex being spread over the axilla. The rest of the wound is covered with Thiersch's skin grafts. The axilla is not drained. The disability resulting after such an extensive operation is surprisingly slight. The entire wound may be closed in most cases by fashioning two flaps from the lower lip of the wound. A small gauze drain should always be placed in the axilla, preferably through a small incision at its posterior margin, in order to drain the large quantity of fluid which escapes from the severed lymph vessels."—(Stewart's *Surgery*.)

PATHOLOGY AND BACTERIOLOGY.

1. *To isolate the microorganism in the blood in a case of streptococcus scpticemia:* "The blood is taken from the median basilic vein. The skin over the vein should be prepared with green soap, alcohol, and bichloride of mercury, as for a surgical operation. The syringe should be of some sterilizable variety which is easily manipulated and does not draw with a jerky, irregular motion. Its capacity should be at least 10 c.c. It may be sterilized by boiling for half an hour. Before drawing the blood, a linen bandage is wound tightly about the upper arm of the patient in order to cause the veins to stand out prominently. When the veins are plainly in view, the needle may be plunged through the skin into the vein in a direction parallel to the vessel and in the direction of the blood-stream. After perforation of the skin, while the needle is groping for the vein, gentle suction may be exerted with the piston. Great care should be exercised, however, that the piston is not allowed to slip back and air be, by accident, forced into the vessel. In most cases no suction is necessary, the pressure of the blood being sufficient to push up the piston. After the blood has been drawn it should be immediately transferred to the proper media (glucose-meat-infusion agar and glucose-meat-infusion broth). At least six glucose-agar tubes should be melted and immersed in water at 45° C. Before the blood is mixed with the medium, the agar should be cooled to 41° C. in order that bacteria, if present, may not be injured by the heat. The blood is added to the tubes in varying quantities, ranging from 0.25 to 1 c.c. each, in order that different degrees of concentration may be obtained. Mixing is accomplished by the usual dipping and rotary motion, the formation of air bubbles being thus avoided. The mouth of each test tube should be passed through the flame before pouring the contents into the plates. Three flasks of glucose broth, containing 100 to 150 c.c. of fluid each, should be inoculated with varying quantities of blood—at least one of the flasks containing the blood in high dilution. The most stringent care in the withdrawal and replacement of the cotton stoppers should be exercised. Hiss and Zinsser use, in place of one of these flasks, one containing, in addition to the glucose, 1 gram of powdered calcium carbonate. This ensures neutrality, permitting (pneumococci or) streptococci, which are sensitive to acid, to develop and retain their vitality."—(From Hiss and Zinsser's *Bacteriology*.)

To prepare a vaccine: "All media and apparatus should be sterilized. Having isolated the organism, it is inoculated upon one or more agar slants, and after a growth of from five to seven hours (with streptococci) the growth on these inoculated slants is taken up with salt solution, thoroughly shaken up in the diluting solution and standardized. The most practical way is to gently rub off the growth on the agar in about 1 or 2 c.c. of salt solution with a platinum loop. Then pour the bacterial emulsion into a sterile test-tube and repeat the process with three to five agar slants, until we have from 6 to 10 c.c. of the emulsion in the sterile test-tube. By heating to melting point in the flame a piece of glass tubing and attaching it to the rim of the test-tube (also melted), we have a handle with which to draw out the test-tube when heated about 1 inch from the mouth in a blowpipe flame. Drawing this out, we let it cool, and then filing the constricted portion we break it off and seal it in the flame. By shaking up

and down vigorously for five to fifteen minutes, the bacteria are distributed evenly in the salt solution. A piece of platinum wire, twisted into corkscrew shape and fused in the draw-out end of the containing test-tube, helps in breaking up the bacterial emulsion. The sealed test-tube is then placed in a water-bath at 60° C. and heated at this temperature for one hour. Again shake. The constricted sealed end is again filed off and a few drops shaken out in a watch glass for standardization, and at the same time a few drops are deposited on an agar slant as a test for sterility. (Incubation for twenty-four hours should not show growth.)" —(Stitt's *Practical Bacteriology.*)

2. *Pathological changes occurring in the lung in acute lobar pneumonia:* "(*a*) The stage of *hyperemia* is very exceptionally observed unless the subject dies in twenty-four to thirty-six hours, although hyperemia may be seen at the edges of the consolidation where the pneumonia is beginning to extend. The lung crepitates less and floats: it is red, tears readily, since it has lost its elasticity, and on section exudes a serosanguineous fluid. Under the microscope, congestion, serum, and diplococci in the alveoli are observed. The alveolar epithelial cells swell and desquamate, which, according to some observers, are the primary changes. (*b*) In the stage of *red hepatization*, the lung is evenly red, friable, airless (not wholly so in pneumonia of an upper lobe), and sinks when put into water. Its weight is increased 10 to 50 ounces. The lung has marks of the ribs on its fibrin-coated surface and is enlarged to the size of deepest inspiration. On scraping the cut surface, fibrinous plugs or casts of the bronchioles are observed. The lung is granular on section, from fibrinous exudation into the alveoli; these granulations are seen best by oblique illumination. Under the microscope, coagulated blood and exudate, alveolar epithelium, injected bloodvessels, emigration of leucocytes, diplococci, and meshes of fibrin are noted. (c) In the stage of *gray hepatization* the granulations are grayish-yellow—not red, because the blood is absorbed; they are larger and looser than in the second stage. The connective tissue is grayer than the granulations, and is sharply defined by the lung pigment. It has been claimed that death always occurs if this stage is reached. If the patient lives, the granulations disappear; the lung exudate becomes semifluid (purulent infiltration) and can be washed out; resorption of this fatty emulsion occurs by the lymphatic vessels and not by evacuation through the sputum. Proteolytic ferments, probably derived from the leucocytes, dissolve the exudate; the products of this autolysis are excreted by the kidneys."—(Edwards' *Practice of Medicine.*)

3. In *myelogenous leucemia*, the *blood* shows a permanent increase in the leucocytes other than the polymorphonuclear variety; myelocytes are present in great numbers, constituting from 20 to 60 per cent. of all leucocytes. The total number is about 300,000 per cubic millimeter as an average, but counts as high as 750,000 have been reported. The number, however, may be as low as 100,000 or even in some the count may approximate the normal. The differential count of the white cells in combination with the usual increase in number is the characteristic feature. The main form is the large mononuclear myelocyte containing neutrophile granules. They may constitute some 35 per cent. of all the leucocytes. The nucleus is situated, as a rule, in the center and is well staining, it may be eccentric, however, or poorly staining. The large cell with the pale nucleus is seldom found in any other condition than in this form of leucemia. The neutrophilic granules may be lacking entirely and the nuclei show hydropic degeneration. Occasionally small myelocytes with deeply staining nuclei may be present. Eosinophilic myelocytes may be found in large numbers, varying from 3,000 to 100,000 per cubic millimeter. Such an increase is pathognomonic of splenomyelogenous leucemia. The ordinary type of eosinophiles is also increased. Basophiles or mast-cells are increased, sometimes very markedly, this condition being quite characteristic of leucemia. Polymorphonuclear neutrophilic leucocytes are relatively diminished as the myelocytes increase, and form about 46 per cent. of the total. They are absolutely increased to 60,000 or 70,000. Degenerative changes are very common, the cells becoming more cohesive, the nuclei pale and showing karyolysis or rhexis, and frequently mitotic figures. Lymphocytes are not very numerous as a rule; they constitute about 10 per cent. although the number may vary considerably. The blood itself may be pale and the specific gravity lowered. Coagulation takes place slowly. The erythrocytes are decreased to about 3,000,000, the hemoglobin is diminished also, 40 per cent., color index about 0.6. Many of them are nucleated and show changes in size and shape. The normoblasts are very common, and megaloblasts are frequently seen.

The *organs involved* are the spleen and bone-marrow. The latter shows a marked hyperplasia, loses its yellow color and becomes dark red. Numerous nucleated erythrocytes and eosinophiles are present. The spleen is much enlarged as a result of a general hyperplasia of both the connective and lymphoid tissue. Grayish, circumscribed areas, due to the infiltration of leucocytes, may be seen. The liver is usually somewhat enlarged, and the lymph nodes may show some hyperplastic changes. Hemorrhages into the serous and mucous membranes and the retina are quite frequent. Fatty degeneration of the viscera generally occurs to some extent.—(McConnell's *Pathology.*)

4. *Relation between the human and bovine types of tuberculosis:* "Widely divergent views are held respecting the danger to man of infection from bovine sources. There are those who, like v. Behring, maintain that the common forms of tuberculosis usually originate in infancy through intestinal infection with milk, and that the bacilli remain latent in the tissues for long periods; Koch and others have declared that the susceptibility of man to bovine tuberculosis is slight, and that infection with the milk, butter, or flesh of tuberculous animals is a very rare occurrence. The question is complicated and its experimental solution presents many technical difficulties. It was first clearly established by the work of Theobald Smith that the bovine tubercle bacillus was a distinct variety or race of the mammalian tubercle bacillus, and as such possessed certain definite and rather constant characters. Some modifications may occur in passing from host to host, but Smith believes that 'the modification of bovine bacilli in the same human body beyond recognition as such by the bacteriologist, if it ever occurs, necessarily presupposes a prolonged sojourn, probably of years at the shortest.' Granting a fair degree of constancy, it follows that tubercle bacilli recovered from the human body may be identified with more or less certainty as of bovine or human origin. A number of observers have encountered bacilli of the bovine type in the human subject, and it is therefore plain that, so far as this line of evidence goes, infection with bovine bacilli can and does take place. At the same time, it must be noted that the fully studied and established cases of this sort are few in number, and that there is still inadequate information respecting the relative frequency with which bacilli of the bovine type are found in human tuberculosis. Inoculation experiments have shown that cattle may be infected with human tubercle bacilli and sputum, contrary to the view at one time enunciated by Koch. Evidence that the converse also may occur is not lacking."—(Jordan's *Bacteriology.*)

Von Pirquet's test is a tuberculin test for the presence of tuberculosis. Two small drops of old tuberculin are placed on the skin of the front of the forearm about two inches apart, and the skin is slightly scarified, first at a point midway between them, and then through each of the drops. In about ten minutes the excess of tuberculin is gently wiped away with cotton. No bandage is necessary. A positive reaction is shown by the appearance in twenty-four to forty-eight hours of a papule with red areola, which contrasts markedly with the small red spot left by the control scarification.

5. *Fixation of the Complement* and *Wassermann test:* "When a substance capable of inciting the body-cells to the formation of antibodies, *i.e.* an antigen, is mixed with its corresponding heated serum, *i.e* antibody or amboceptor, in the presence of complement, the latter is so "fixed" in combination with the antigen that it is no longer free to enter into any other combination. This is shown by the fact that if such a mixture be placed in contact with the sensitized red blood cells, no hemolysis is produced. If, in the above reaction, the heated serum contained no antibody, the complement would not be fixed and hemolysis would take

place on the addition of the sensitized red blood cells. In this way one may determine the presence in given fluids of specific antibodies, on the one hand, or of antigens on the other, if he have at hand the homologous antigens or antibodies as the case may be. For antigens one may use bacteria or bacterial extracts. In *Wassermann's test* it was assumed that syphilitic organs might contain uncombined portions of products of Spirochæte (Treponema) pallidum, *i.e.* free syphilitic antigens, and thus extracts in salt solution or alcohol were made of organs—spleen, liver, etc.—of a syphilitic fetus. But it was discovered later that specific antigens are not necessary for the reaction; that extracts of normal organs, liver, spleen, heart, human or animal, or lecithin in solution can act as antigens in the tests."—(Delafield and Prudden's *Pathology.*)

Value of the Wassermann test: A well-pronounced positive reaction probably indicates the presence of syphilis; but leprosy, sleeping sickness, and scarlet fever must be ruled out. Cancer is also said to give a positive reaction. It may indicate that the patient *has* syphilis, or that he has *had* it. The test requires elaborate technique at the hand of an expert.

6. *Tumors of the breast* may be *classified* as benign and malignant. The *benign tumors* are fibroma, fibroadenoma, myxoma, lipoma, adenoma, papilloma and enchondroma. The *malignant tumors* are sarcoma and carcinoma (including epithelioma).

"*Fibro-adenoma* is the commonest benign tumor in the breast. It arises as an adenoma, or proliferation of epithelial cells and increase of acini, surrounded by fibrous tissue (or possibly as a fibrous tumor enclosing glandular acini, *adeno-fibroma*). Two varieties are recognized microscopically; in one of which, the commonest, the acini form small clusters imbedded in a considerable amount of fibrous tissue; in the other they are of a more tubular shape, and are dilated at intervals to form cysts (*cysto-adenoma*), into which project outgrowths of fibrous tissue covered with epithelium. In neither case is the basement membrane encroached upon by the epithelial cells. The tissue outside the acini is either well-formed fibrous tissue; or it is soft and gelatinous (*myxo-adenoma*); or in other cases it is composed of elementary connective tissue resembling sarcomatous cells."—(Buchanan's *Surgery.*)

Epithelioma, or squamous-celled carcinoma, may arise on any surface covered with stratified epithelium. It usually arises in the middle-aged or elderly, but may also occur in the young. It often results from long-continued irritation, and may arise in old scars or ulcers. It may appear in one of three forms: (1) A wartlike growth with an indurated base; (2) a small circular ulcer with raised, rampart-like edges; (3) an indurated fissure. The growth extends to the deeper structures; the surface ulcerates and becomes foul from contamination with putrefactive organisms. The nearest lymphatic glands always become infected sooner or later, and a fatal termination occurs rapidly unless treatment is early and thorough. Secondary deposits, except in the glands, are rarer than in glandular carcinoma. The glands sometimes undergo cystic change, invade the skin, ulcerate, become foul, and may cause death by secondary hemorrhage from ulceration into large bloodvessels. Microscopically, columns of cells are seen extending from the epithelium into the underlying tissues, and interlacing with one another. In some of the columns concentrically arranged masses of flattened, cornified cells occur, called "cell nests." The tissues immediaately surrounding the growth are infiltrated with small round cells.—(*Aids to Surgery.*)

Total German Casualties.—According to a Holland periodical the names of German soldiers already published in casualty lists, inclusive of prisoners, but not of the victims of disease, occupy 22,000 printed pages. The actual number of names, which may include some duplication, is more than 8,000,000.—*Pathologia.*

Undernourishment in Sweden.—While not at war, Sweden nevertheless is evidently suffering from the effects of undernourishment, for, according to dispatches from Copenhagen, an endemic dropsy has made its appearance in that country. There are numerous victims, especially among the working classes.—*El Siglo Médico.*

Therapeutic Hints.

Treatment of Gunshot Wounds.—Major Charles W. Duggan, R. A. M. C. (retired), writes in the *Therapeutic Gazette* in praise of ichthyol and glycerin in the treatment of gunshot wounds. He uses equal parts of ichthyol and glycerin, as long as there is suppuration—an average period of three days, and then reduces the strength of ichthyol to 20 per cent. The combination is painted on the surface of the wound and the surrounding skin by means of a camel's-hair brush and the parts are then covered with antiseptic gauze and cotton wool retained by a bandage. An impermeable dressing, such as oiled skin, should not be used as it would inevitably delay the healing process. When the dressing is changed the surface is dried with sterilized cotton-wool and occasionally dabbed with alcohol, but not washed.

Formalin for Ingrowing Toenail.—Suldey advises application of a solution of formaldehyde (formalin) for the relief of ingrowing toenail. A pledget of cotton wet with formalin is swabbed over the granulations once every day. The pain is relieved almost immediately, the inflammation is rapidly reduced, and the cure is practically complete in four or five days.—*Journal de Médecine et de Chirurgie Pratiques.*

Treatment of Grippe Pneumonia with Plasma from Convalescents.—Grigaut and Moutier have practiced the intravenous injection of the blood plasma of convalescents, the plasma varying in age from 4 to 8 hours and the amount from 50 to 500 c.c. for each 24 hours. The method was found to be quite harmless. In regard to efficacy, much depends on the date of the injection. When given early in the case a favorable influence was at once apparent. After the fifth day no benefit was apparent. The total number treated was 10, of which 8 received the injections before the third day. The crisis in these cases came about within 24 hours. Sometimes 60 c.c. were sufficient to produce this result. The massive doses were used only in the most serious cases.—*Le Progrès Médical.*

Acute Tonsillitis.—The best remedy for acute sore throat—acute tonsillitis—is Vichy water, in medium or large doses, according to the severity of the case, taken on an empty stomach.—*De Castro Pérez.*

Fibrinous Pneumonia.—Give medium or large doses, according to the case, of sodium bicarbonate on an empty stomach.—*De Castro Pérez.*

Asthma.—Bensaude and Hallion advise a mixture of pituitary extract, the equivalent of 0.25 gram of the fresh gland, and one-half milligram of adrenalin chloride, to be given hypodermically once a day. Relief is usually experienced within five minutes, and the effect persists for a day or longer.—*La Presse Médicale.*

Gastric Acidity.—Gaston Sardou recommends sodium citrate for this condition, and says the salt is better tolerated by weak stomachs if it is given in the nascent state. He makes a solution of 15 grains of sodium bicarbonate in a glass of water and adds thereto a teaspoonful of lemon or lime juice, the potion being taken as soon as effervescence has ceased. A little magnesium hydrate may be added to increase the tolerance.—*Journal des Praticiens.*

TWO HUNDRED AND FIFTY MAJOR OPERATIONS UNDER LOCAL ANESTHESIA.*

BY JOSEPH WIENER, M.D.,

NEW YORK.

ASSOCIATE SURGEON MOUNT SINAI HOSPITAL.

WHAT a far cry it is from the pioneer work of Corning, Reclus, and Schleich, with their massive intradermal infiltration of dilute cocaine solutions, with their limited field and their ever-present danger of poisoning, to the modern synthetic compounds with which we can work for an hour or longer, using as many grains as we desire, with no danger of any constitutional manifestations, and yet with complete anesthesia of the tissues. To quote from Matas, "The synthetic chemists and pharmacologists have not been idle, and their untiring and brilliant efforts to find substitutes for the dangerous and costly cocaine have given us a succession of remarkable synthetic products. In like manner, the genius of synthetic chemistry and the biologic laboratory have found in suprarenin a less perishable substitute for adrenalin. The advent of adrenalin and its synthetic substitutes has marked a new era in the history of local anesthesia. By its powerful and lasting vasoconstrictor and ischemic action it gives the operator a bloodless field, which has deserved for it the name of chemical tourniquet (Braun).

What do we expect of the ideal local anesthetic? (1) It should be non-toxic. (2) It should produce a durable anesthesia. (3) It should cause as little local disturbance as possible. (4) It should be soluble in water, compatible with adrenalin and sterilizable by heat. Today we have two synthetic compounds, both belonging to the ester group, both having an amido base, that stand far above all other anesthetics. I refer to novocain and apothesine. They differ in two essentials. Novocain is made with ethyl alcohol and benzoic acid, and apothesine with propyl alcohol and cinnamic acid. Shortly after we entered the war, the U. S. Government requisitioned most of the available supply of novocain. About that time a chemist from one of our large drug manufacturing companies came to me with samples of apothesine and asked me to give it a trial. Since then I have been using it exclusively. It is not a derivative of cocaine, is not a habit-forming drug and is not subject to the Harrison law. According to the manufacturers apothesine is the hydrochloride of gamma-diethyl-amino-propyl cinnamate. It occurs as a small white crystal having a melting point of 137 degrees Celsius. It is readily soluble in alcohol, slightly soluble in acetone and ether, and readily soluble in water. The solution in water is neutral to litmus. It is precipitated from solution by alkalies and by the ordinary alkaloidal reagents. As is the case with all anaesthetics and alkaloids, the best results are insured by the use of freshly prepared solutions." Novocain, discovered by Einhorn in 1905, is the diethyl-amino-ethanol ester of paraaminobenzoic acid. Like other synthetic compounds, novocain and apothesine diffuse slowly through the tissues and a reasonable amount of time should be allowed for the anesthetic to act. I have been in the habit of referring to operations under local as D. L. and W. operations—delay, linger, and wait. In my hands there has been no interference with the healing of wounds. I have often been asked about the toxicity of apothesine. I have used as much as twelve grains at one sitting and have never seen any sign of toxicity. By mistake of a nurse one patient was given 6 grains in solution to drink; I then injected 6 grains and removed a perforated appendix, and there were no signs of any toxic effect. Just how much it is safe to use I do not know. As far as my experience goes apothesine is not a toxic drug. My experience coincides with that of Arthur D. Bevan, who wrote in 1917, "I have recently used apothesine in twenty-five operations, including removal of inguinal glands, resection of rib and drainage of lung abscess, circumcision, inguinal and femoral hernia, carcinoma of the face, ligation of thyroid vessels, gastroenterostomy, drainage of subphrenic abscess, and a very extensive thyroidectomy. We have used as large an amount as five and one-half ounces of a one-half per cent. solution. We have not noticed any toxic effect of any kind and no interference with primary wound healing."

To show how important the details of the technique are, I would refer to the fact that one of the masters of local anesthesia, Prof. Braun, gave it up for appendicitis because his results were not satisfactory. He tried to anesthetize all layers of the abdominal wall before operation and failed. We anesthetize layer by layer and get complete anesthesia. Owing to this fact, a large proportion of my work has been in the field of acute and chronic appendicitis. To my mind one of the great advantages of apothesine is the fact that we can look forward to a steady supply of the drug. Coming, as it did, at a time when the foreign supply of novocain was almost cut off, it was doubly welcome. That it has stood the acid test of time and is at least the equal of the best synthetic local anesthetics we have ever had from abroad, must be a source

*Read before the New York County Medical Society, December 23, 1918.

of gratification to us all. Bevan, Allen, and other surgeons who have used it are well satisfied. The experience of these men coincides with my own. Even when large amounts were employed there were no toxic or unpleasant after-effects. Most observers agree that its action is intensified by the addition of a small amount of adrenalin, and that has also been my experience. My own impression is that anesthesia acts more quickly and lasts longer when adrenalin is used, although I frequently have operated without using adrenalin and have obtained complete anesthesia. A few cases of marginal necrosis of the wound following its use have been reported by various surgeons. I have had no similar experience. If the marginal necrosis is due to the drug—which I doubt—it may be due to faulty preparation of the solution or to faulty sterilization. I think I have had a sufficiently large number of cases to have encountered this result if it were due to the anesthetic. Of course we sometimes get a marginal necrosis of the wound when no local anesthetic is used. And I can testify to having seen such necrosis in days gone by, when I still used alypin as a local anesthetic. Adrenalin played no role in producing skin necrosis in these earlier cases where alypin was used. For it is only in the past few years that adrenalin has been extensively employed in conjunction with local anesthetics. Prof. Heinrich Braun of Zwickau, Germany, deserves the credit for this great addition to our technique. For years he was an ardent worker and writer in the field of local anesthesia, and it is due to his writing that adrenalin has been so widely employed as a valuable adjunct in local anesthesia solutions. When there is no adrenalin in the apothesine tablets, I use five drops of a one to a thousand solution of adrenalin to the ounce of the anesthetic fluid. The solution regularly turns to a light pink on boiling if adrenalin is present. The amount of capillary oozing is very much lessened when adrenalin is used and this anemia lasts usually an hour. I fully agree with Allen when he says "the advantages of this anemia are the greater facility and freedom with which delicate dissection may be performed in a comparatively bloodless field. Aside from the hemosstasis, the most notable gain derived from the use of adrenalin is its power to retain the anesthetic agent within the tissues for a considerable length of time. This retention within the tissues intensifies the anesthetic action and lessens the likelihood of repeated injections being necessary in a prolonged operation. When adrenalin is used the trauma of repeated infiltrations upon the tissues is avoided and the possible toxic action of such constant infiltrations is eliminated. The likelihood of any toxic action developing is lessened, even if the solution injected be retained in the tissues a long period of time. When absorption does occur it is so gradual that no constitutional effects are to be noticed."

Novocain and apothesine can be sterilized either by boiling for a few minutes, or by placing the solution, contained in a bottle, in the sterilizer with the dressings and leaving it there fifty minutes. The mouth of the bottle should be stopped with absorbent cotton to prevent excessive evaporation of the solution. To prevent its decomposition the ordinary solution of adrenalin usually has added to it hydrochloric acid and some antiseptic such as thymol. In this form the adrenalin solution can be sterilized by heat and, if placed in a dark bottle, can be kept a long time; the addition of any alkali will tend to cause decomposition of the adrenalin. But in the tablet form both adrenalin and novocain and apothesine keep very much better than in solution. It is difficult to sterilize the tablets; they should be dissolved in water and sterilized just before use. I usually make up enough for each operation separately.

Lennander has shown, both at operations and experimentally, that the principal parts of the abdomen that are sensitive are, the anterior and the posterior parietal peritoneum, pelvic peritoneum, and the peritoneum covering the diaphragm, as far as it is innervated by the spinal nerves. The visceral peritoneum, stomach, intestines, omentum, and the peritoneal covering of the gall-bladder, liver, and kidneys, are quite insensitive. However, pulling on these organs may cause pain or nausea. I have always found the wall of the stomach, as well as of the intestines, free from sensation, and have clamped or incised without causing any pain. The fundus of the gall-bladder can be clamped and cut without causing pain, but if the gall-bladder is pulled on forcibly, pain will be elicited. The introducing and removing of large gauze packings is distinctly painful.

Why should we use local anesthesia at all? First and foremost to avoid the dangers to life of a general anesthetic. How great these dangers are in any given case we do not know. Some apparently good risks take anesthesia very badly; other patients who seem bad risks, take it well. But that there is a risk to life in every general anesthetic used there can be no doubt. Statistics of anesthesia mean very little. As the witty Talleyrand said, "La statistique c'est le mensonge en chiffres"—statistics are lies in the shape of numbers. And we must not forget that the mere fact that a patient does not succumb during the first few days after operation does not always mean that the danger from the anesthetic is over. Who of us has not seen an aspiration pneumonia—I mean a real "Schluck-Pneumonie," as the Germans called it, prove fatal five or more days after operation. How often does a nephritis date from an operation. Did the operation cause the nephritis? Certainly not, but the ether did. How often have we seen so-called paralytic ileus following abdominal operations? Did the operation cause the ileus or was it the ether? How often have we seen patients after abdominal operations vomit for days and then die exhausted. Did the operation cause the vomiting or was it the ether? I have operated on several peritonitis cases under local anesthetics and it is surprising how little the patients vomit, how little the abdomen is distended, and how quickly they recuperate. In fact I consider a peritonitis a distinct indication for the use of local anesthesia. When we consider that the system is already struggling to throw off a peritoneal infection, and that the organs of excretion are doing a large part of this defensive work, the danger of handicapping these organs still further by giving an anesthetic, must be apparent. And if we can remove an offending appendix, or other lesion, in the presence of a peritonitis under local anesthesia, we are giving our patient a far better chance for a rapid recovery.

Increasing experience but serves to strengthen the conviction that I expressed in one of my earlier papers, that much of the danger from most major operations is the danger of the anesthetic. Much of the postoperative morbidity, many of the complications and not a few of the deaths, should be called not postoperative but postanesthetic. Much of the postoperative distention, gastric as well as intestinal, much of the pain, the inability to move the bowels, the cardiac weakness, and many other of these so-called postoperative complications, are in reality postanesthetic, for many of these complications are either entirely absent, or very much lessened when local anesthesia is used. And with some operations we can say positively that the mortality is lower when local anesthesia is used; *e. g.* gastrostomy and gastroenterostomy for carcinoma, strangulated hernia operations with or without resection of gut, and appendicitis with peritonitis. I have done these various operations with and without anesthesia and I feel sure that some of these cases, alive to-day, owe their lives to the use of local anesthesia. The same is true of two cases of radical amputation of the breast for carcinoma in advanced cardio-nephritic cases. This applies also to an old man of sixty-four with icterus and much loss of weight, whose gall-bladder I removed and whose common duct I split under apothesine. This old man felt so well that he wanted to leave his bed two days after operation. To anyone who has not followed these cases it seems like a gross exaggeration to portray their remarkable postoperative comfort and well-being.

How often are we confronted by patients who, we say, are bad operative risks, when we mean they are bad anesthetic risks. Take some of these patients and give them ether for forty-five minutes or longer, and do no operation on them at all, and they will have a stormy time for several days, and some of them might even die as a result of the anesthetic. It is a well known fact that patients are much less uncomfortable and have less postoperative complications after a short than after a long operation. This means they have had less ether and therefore are less sick. If we take away the ether altogether, is it not natural to expect a much smoother convalescence?

But are there any inherent objections to operations under local anesthesia? Surely there are, or else all surgeons would be using it much more freely than they do. First is the fear of causing pain. With increasing experience, with proper technique, and with careful selection of cases, pain can to a large extent be eliminated. And even if pain were not entirely eliminated in some cases, the lessened danger of the operation, the fewer postoperative complications, the wonderful difference in postoperative comfort, would weigh heavily in favor of such procedure. That operations under local anesthesia take more time is true, but if we figure ten or fifteen minutes to get the patient under ether, the difference in time in many operations will not be marked. One objection is a real one. It is more trying for the surgeon to operate under local than under general anesthesia. There is the additional mental strain of encouraging the patient to keep quiet and to keep up his courage. It takes many months of careful painstaking feeling one's way, as it were, before the surgeon has acquired the requisite experience and has perfected his technique sufficiently to warrant his undertaking major operations under local anesthesia. And that the preparatory course of training is often a most trying one I can truthfully testify. Much greater care and gentleness must be used in handling the tissues, or the patient will have pain. Added to this is the consciousness that any slight error in the technique will cause pain. The cooperation of an intelligent patient is a greater help. That is the reason why so large a percentage of my cases were private cases. In any case, we can arrange our day's work so that not too many operations under local anesthesia are done at one sitting. Even if it is much more trying to do major operations without general anesthesia, should we not sacrifice our personal comfort for the great advantages that accrue to the patient? The answer to that question will in large measure determine the field of usefulness of this procedure in the hands of each individual surgeon.

It is important to gain the confidence and cooperation of the patient. I operated on a nervous young woman, who required considerable persuasion to allow me to remove her appendix under local anesthesia. As I was sewing up the wound she asked me to repair her lacerated perineum. I offered her ether for this, but she would not hear of it. Whereupon I did a colpoperineorrhaphy under local anesthesia, and the patient assured me that both operations were quite painless.

We have repeatedly had two and three cases of appendicitis operated on under local anesthesia in the ward at the same time, and the patients who had been through it usually encouraged the new ones to have it done. When we consider the character of our ward patients, we can be quite sure that this would not have been the case if the operations had not been painless.

Some hospital patients who complained during the operation assured me later that they had simply been frightened and that the pain was really trivial. Various patients who had previously been operated on under ether assured me that they would never again want to take ether for an operation. The difference in the postoperative comfort is so striking that all these patients commented on it. I removed the appendix of a gentleman one afternoon and the next morning his wife came in and found him reading the paper. She was astounded at the absence of all pain and discomfort. Her own appendix had been removed under ether, and she assured me that her suffering from abdominal distention for forty-eight hours after operation had been more severe than her labor pains. A physician, whose appendix I removed one evening during an acute attack, was phoning to his patients the next morning. And these are not isolated cases. The absence of postoperative pain and discomfort is a very striking feature of almost all cases done under local anesthesia.

Pain during Operation.—Almost all of the patients who complained of pain during the operation said later that they had had very little pain, but that they had been afraid. One young lady fell asleep during an operation for femoral hernia. She woke up and was surprised to hear that the operation had been completed. Both patients on whom a radical amputation of the breast for carcinoma

was done assured me that the pain during the prolonged operation was trifling.

Postoperative Distention.—This was strikingly absent in almost all of the cases, and I consider this one of the great advantages of local anesthesia. I usually give one c.c. of pituitrin hypodermically on the day after operation, and follow it in half an hour with a rectal irrigation or a high enema. Most of the postoperative pain and discomfort is due to inhibition of peristalsis caused not so much by the operation as by the anesthetic. If local anesthesia did nothing else than eliminate this, it would well be worth while. One of the striking facts in these patients is that they usually pass gas on the day after operation. In one case of empyema of the appendix gas was passed voluntarily twelve hours after operation, and neither enema nor cathartic was given during the entire convalescence.

Nausea and Vomiting.—With exception of the peritonitis and abscess cases, nausea and vomiting have been almost uniformly absent in our cases. Only in the exceptional cases have we seen it.

Opiates after Operation.—The average number given was two and a quarter. The largest number given was four and this was necessary only in very few cases. Several patients received only one hypodermic during the entire after treatment.

Postoperative Course.—The postoperative course is in striking contrast to what we see in cases that have had ether. A few hours after operation there is a little wound pain which is easily controlled by codeine or a little morphine. The restlessness, nausea, and vomiting that usually follow the use of ether are entirely absent. The patients greet you with a smile the next morning and usually express their surprise that they have so little discomfort. Peristalsis is usually established early, and the troublesome and painful postoperative distention is entirely absent. A hypodermic injection of one c.c. of pituitrin on the day after operation adds to the comfort of the patient. Almost all of the patients have been able to take and retain fluids within a few hours after operation. There is an entire absence of the mental depression so common with ether. The patients usually get out of bed sooner than if ether is given. In short, smooth and rapid convalescence, even in the acute cases, is a most gratifying phenomenon.

The cases which furnish the basis of this paper are divided into hospital and private.* The hospital cases are from the first surgical service at Mount Sinai Hospital. A few of the cases were operated on by members of the house staff. The private cases were operated on at various hospitals and sanitariums and some at the patients' homes. In several of these I found out after operation that relatives were anxiously listening outside the door to catch any sound of distress from the patient. Repeatedly I had an anesthetist ready to give ether if necessary, but in none of these cases, done at home, was there any complaint from the patient and in none of them was a general anesthetic used. I have not done any major operation under local anesthesia in a patient under fourteen years; the oldest patient, a case of strangulated hernia, was ninety-one years old. This old lady did not know that an operation was being done; she was told that the hernia would only be reduced. I was able to do a radical operation and she was puzzled for a week to know why we had bandaged up the parts.

I shall not give a detailed account of the forty cases done under local anesthesia before 1916. They were operated on with various of the earlier local anesthetics—eucaine, stovaine, alypine, etc. Complete data of these earlier cases are not at hand, and moreover they were done before my present technique was developed and were done more or less as operations of necessity under local anesthesia. These earlier operations included suprapubic cystotomy, herniotomy, gastrostomy, tracheotomy, and a few cases of intestinal resection in strangulated hernia. But during the years preceding 1916 my work under local anesthesia was of the desultory kind such as most surgeons did at that time. Since 1916 I have asked myself not what is the contraindication to a general anesthetic in a given case, but rather what is the contraindication for local anesthesia. And it is surprising how the number of operations in which local anesthesia can be satisfactorily employed has increased. This is especially true among intelligent private patients, who are only too glad to escape the dangers and discomforts of general anesthesia. And so it is that I am able to report eighty-eight major operations on private patients in the past three years. And a goodly number of these patients are being sent by other patients, who had been operated on under local anesthesia. And several doctors and nurses are among the most enthusiastic patients of this class.

Technique.—During the past three years I have from time to time made changes in the method of procedure. The technique which I now employ is as follows: Three-quarters of an hour before operation the patient receives a quarter of a grain of morphine hypodermically. Unless the patient appears drowsy this dose is usually repeated just before operation. I use a 1 per cent. solution of novocain or aposthesine to an ounce to which five or six drops of a one-to-a-thousand solution of epinephrin have been added. Tablets of apothesine with epinephrin are a great convenience. One ounce of the anesthetic solution usually suffices for a herniotomy or an appendicitis operation. While I am in the habit of using a 1 per cent solution, it is true that weaker solutions will often give complete anesthesia. By mistake I once did two successive operations for appendicitis at a private sanitarium with a one-third of 1 per cent. solution of apothesine, and both operations were entirely painless. But I believe that a quicker and more satisfactory anesthesia is obtained with a 1 per cent. solution. In appendicitis operations I regularly use the muscle splitting McBurney incision and it is particularly well adapted to the operation under local anesthesia. Its great advantage is the fact that it comes right down on the cecum. Not only is it rarely necessary to pack away the intestines, but there is very little handling of the intestines. The first injection of the anesthetic is not under the skin but into the skin along the line of proposed incision. In doing this the skin should be blanched by the solution. As soon as this has been done I pass the needle into the deeper tissues and inject some anesthetic. The advantage of this is that while we are waiting for the skin to become anesthetic some of the

*Of the 210 major operations performed under local anesthesia in the past three years, 88 were on private patients and 122 on hospital patients.

deeper tissues are being partially anesthetized. It is very important to have the skin thoroughly anesthetized, so that you gain the confidence of your patient at the beginning of the operation.

After waiting two or three minutes the skin and subcutaneous tissues are divided. I always use a sharp scalpel for dividing all layers, as scissors being blunter are more apt to cause pain. The anesthetic is next injected under the aponeurosis of the external oblique and also into the internal oblique muscle. After two minutes both these structures can be painlessly divided. The needle is then passed obliquely under the peritoneum to prevent the possibility of its injuring a coil of intestine and a few drops of anesthetic are injected. After two minutes the peritoneum is divided. Done in this way there will be no pain up to this point. Both operator and assistants should handle the tissues with the greatest gentleness.

As soon as the cecum with the appendix is exposed a catgut ligature is passed through the base of the mesentery close to the appendix. This ligature is not tied, but is used as a tractor to draw the base of the appendix into the field of operation. As soon as the base of the appendix is exposed the anesthetic is injected freely into its mesentery. I omitted to do this in my earlier cases and the patients usually complained of cramps referred to the epigastrium or umbilical region. Sometimes I wait a minute after injecting the base of the mesentery and then pull on the ligature and expose the balance of the mesentery, which is then anesthetized in its entire length. Sometimes it is possible to inject the anesthetic into the entire mesenteriolum as soon as the base of the appendix is exposed. I have not found it necessary to anesthetize the mesocecum. It can be done readily enough, but in our experience it is unnecessary. A few minutes after injecting the mesentery, the appendix can be pulled out of the abdomen, the mesentery ligated and divided, and the appendix removed with no pain. It is not necessary to inject the anesthetic into the base of the appendix. I have operated on many cases with adhesions. Fibrous adhesions are not sensitive and can be readily divided. Omental adhesions are readily anesthetized by injecting a few drops of the solution. In a few minutes the adhesions can be painlessly ligated and divided. If necessary the right tube and ovary can be drawn into the wound and resected. The closure of the wound in layers is unusually painless. Of late I have been leaving a small drain under the skin to prevent a collection of serum which sometimes occurs with local anesthesia. This little drain is removed at the first dressing.

In my earlier herniotomies I was in the habit of blocking the iliohypogastric and ilioinguinal nerves. Of late I have given this up and now use the anesthetic in all the layers of the abdominal wall as described above. I always inject some anesthetic into the neck of the sack, as this is usually sensitive.

Time of Operation.—Including both the acute and chronic cases of appendicitis the average time was twenty-two minutes. Almost half of the time is consumed in waiting for the anesthetic to act. Furthermore, and this is another advantage of the procedure, as the patients are conscious all their tissues must be handled much more gently and deliberately. All this time is time consuming, but is of great advantage to the patient in the course of the after-treatment. While it is true that the ordinary operation for appendicitis under ether takes only twelve to fifteen minutes, we must not forget that it takes five to ten minutes to get the patient under ether. After all, in operations under local anesthesia, the element of time is of very little importance. The ordinary inguinal hernia operation takes but little longer under local anesthesia than under ether. I have repeatedly completed the double inguinal hernia operation within an hour. The two cases of radical amputation of the breast for carcinoma, done entirely under local anesthesia, took an hour each, and at the end of that time there was still complete skin anesthesia, so that the skin could be painlessly sutured. The longest operation I have done was the removal of carcinomatous glands of the neck, and this took one and a half hours. I this case I injected apothesine several times during the course of the very difficult dissection. Most operations take a little longer under local anesthesia; and, as mentioned above, a satisfactory operation under local anesthesia must be done slowly and deliberately. There is no harm in having an eye on the clock, but this should be done in order to see that enough time elapses after injecting the anesthetic before proceeding to incise each layer. When I have several cases to do in succession I have one of the assistants sew up the skin and apply the dressings while I am injecting the anesthetic into the next case. By following this method I was able from 2.30 to 5 P. M. to operate on the following cases under local anesthesia: (1)—Gastroenterostomy through a Sprengel incision. (2)—Division of peripyloric adhesions through Sprengel incision. (3)—Acute appendicitis. (4)—Suprapubic cystotomy.

Appendix.—Of the 115 acute and chronic cases there were two deaths which are referred to below. To show the kind of cases that can be operated on under local anesthesia, I append the following histories:

CASE I.—Irving R., twenty-four years old, admitted to Mount Sinai Hospital July 27, 1916. Two days before admission he had been seized with abdominal pain which became localized in the right iliac fossa. The pain gradually increased and vomiting set in. Examination showed a distended abdomen, with tenderness and rigidity in the right lower quadrant. Temperature, 101.6° F.; pulse, 96. Immediate operation for gangrenous perforative appendicitis with spreading peritonitis. In spite of the marked tenderness, the abdomen was opened painlessly, through an intermuscular incision. On opening the peritoneum free turbid, foul-smelling fluid was evacuated. The appendix, which was surrounded by a dense plastic exudate, was completely gangrenous, filled with pus, and contained several coproliths. The adhesions and the plastic exudate were infiltrated with novocain, and the appendix was removed. A drain was introduced and the wound sutured. The operation took twenty-seven minutes and was associated with very little pain. During the after-treatment a pelvic abscess which developed opened spontaneously into the rectum. The man made a good recovery.

This was certainly a case that tested the method severely. In spite of the pain and tenderness the abdomen was opened painlessly. In spite of the gravity of the lesion and the presence of a peritonitis and of extensive dense adhesions, we were able to do the operation completely under local anesthesia with very little discomfort to the patient. It is just in this class of cases with peritonitis that we believe the greatest field of usefulness for the

operation exists. If such a patient is given ether he is exposed to the danger of a nephritis or a pulmonary complication, which may be just enough to turn the scale against him and cause his death. How much better is such a patient able to throw off his infection if he is saved the all too common postoperative distention, nausea and vomiting, with its concomitant extra strain on the circulation! I firmly believe that in this class of cases local anesthesia will often be a life-saving procedure.

Case II.—George H., forty-two years old, admitted to Mount Sinai Hospital January 31, 1917. Eleven days before admission he had been suddenly seized with severe pain in the right iliac region, which was not relieved by cathartics. The pain had persisted since the onset. Temperature, 100.4° F.; pulse, 100. There was moderate rigidity over the lower right rectus and tenderness over McBurney's point. Operation February 1, 1917, for gangrenous perforative appendicitis with abscess. On opening the abdomen through an intermuscular incision a large amount of thick, foul pus was evacuated. In the abscess cavity a free sloughing mass, the size and shape of the appendix, was found and removed. Two large coproliths were also removed from the abscess cavity. The wound was closed with drainage. Time of operation was thirty minutes. Recovery was uneventful.

Case III.—Gertrude L., nineteen years old, admitted to Mount Sinai Hospital January 7, 1917. Four days before admission she had been seized with epigastric cramps, which soon settled in the right iliac fossa. She had vomited several times and had repeatedly felt chilly. There was considerable tenderness and rigidity in the right iliac region. Temperature, 102° F.; pulse, 88. Immediate operation for gangrenous appendicitis with diffuse peritonitis. On opening the abdomen free turbid fluid was found. The cecum was mobilized with great difficulty on account of adhesions. The appendix was found retrocecal, adherent, gangrenous, imbedded in an inflammatory mass. Novocaine was injected into the adhesions before dividing them. The appendix was then painlessly removed, and the abdomen closed with drainage. Time of operation was thirty-six minutes. Convalescence was delayed by a femoral phlebitis, but was otherwise uneventful.

In this case, too, the patient was surprisingly comfortable when the severity of the case is considered. The first two days after operation were a great contrast to what we usually see in peritonitis cases operated under ether. There was none of the restlessness, vomiting, tympanites, and severe pain which are so trying to the patients and to the attendants. In fact, the absence of these symptoms in our acute cases is one of the most gratifying features of the procedure.

Of the many other interesting cases, the following are selected to give some idea of the scope of operations under local anesthesia:

Case IV.—Subphrenic Abcess.—Mrs. X. was an old lady who had symptoms of subphrenic abscess, but repeated aspirations by various men failed to show pus. The radiograph showed a large shadow in the region of the right subphrenic space. I resected the eighth rib in the axillary line and sewed the two layers of pleura together. I then aspirated through the diaphragm, found pus, and opened an abscess containing at least 8 ounces. The operation, done under local anesthesia, presented no difficulties, and the patient made a good recovery.

Case V.—Resection of Metatarsus, and Phalanx for Infected Bunion.—The patient was an old gentleman of sixty-two, who had a bad heart, and both his physician and his family were opposed to his taking ether. I made incisions on the dorsal and plantar aspects of the foot to drain the cellulitis, excised the infected bursa, resected the base of the phalanx of the big toe and also the head of the metatarsus, which was badly infected. I used novocaine freely in the soft parts, after applying a Martin bandage to the leg, and I was careful to inject novocain under the periosteum of the phalanx and of the metatarsus. At no time during the rather extensive operation did this old gentleman complain of pain.

Case VI.—Resection of Thrombosed Femoral Vein.—Miss K., a trained nurse, after lifting a heavy patient, had suddenly noticed a swelling in her left groin. Immediately thereafter she had vomited and fainted. She was employed at that time in one of the German University clinics. The attending surgeon diagnosed femoral hernia, and she was given ether preparatory to having it operated on. Before the operation had been started she collapsed, and was resuscitated only with great difficulty. No operation was attempted and she was told that she should never try to take ether again. For ten years following this experience a small swelling remained in the groin, but did not cause much discomfort. She then began to have pain in the left leg and thigh at frequent intervals, with occasional swelling of the foot and leg. During all this time the diagnosis of femoral hernia was adhered to. I first examined this case eighteen years after the onset of the trouble. I found a small elastic swelling in the left groin just below Poupart's ligament. It was quite tender and not reducible. There was no evidence of any varicose veins and I concurred in the diagnosis of irreducible femoral hernia. At the operation done under local anesthesia I was very much surprised to find that the swelling consisted of the enormously distended common femoral vein which was filled with a firmly organized clot. I resected the vein and the patient made a good recovery, and has had no further trouble.

Case VII.—Cholecystectomy and Choledochotomy for Cholelithiasis and Cholangitis.—B. G., a man of sixty-five years, in poor general condition, had lost 15 pounds in weight. Four weeks preceding operation he began to complain of pain in the epigastrium and right hypochondrium. He had had chills and fever and was deeply jaundiced. The liver was enlarged and a mass was to be felt below it. His coagulation time was eight minutes. Through a Sprengel cross incision the gall bladder, which contained stones and infected bile, was removed. The common duct contained a stricture which was divided. This old man had very little pain during the extensive operation and tolerated all necessary manipulation. He made a very rapid, smooth recovery, and has remained well during the ten months that have elapsed since operation. This man came to operation in very poor condition and would certainly have been a distinctly bad risk for general anesthesia. He was the patient, referred to above, who felt so well that he wanted to leave his bed two days after operation.

Case VIII.—Gastroenterostomy for Pyloric Ulcer.—Eva K., fifty-three years old, was admitted January 28, 1918. She had lost 40 pounds in ten months and complained of pain in the upper abdomen, accompanied by a feeling of fullness after meals. Gastric analysis showed food retention, epithelial and blood cells. Through a Sprengel incision a typical posterior gastroenterostomy was done with Connell sutures. The operation was entirely painless and the patient was discharged in fifteen days.

Case IX.—Posterior Gastroenterostomy for Pyloric Obstruction.—Mr. C., a gentleman of sixty-seven, had a gastric history of many years standing. Radiographic pictures showed no tumor, but almost complete closure of the pylorus, with great dilatation of the stomach. He had been vomiting several times daily for many weeks and was very much emaciated. At operation a mass was found at the pylorus which had the appearance of being inflammatory. A typical posterior gastroenterostomy was done with sutures. This old gentleman complained of no pain at any time during the operation. His vomiting stopped and his general condition improved.

Case X.—Cholecystectomy for Chronic Cholecystitis.—Lillian M., forty years old, had been complaining for ten months of severe attacks of pain in the right hypochondrium. There has been jaundice in some of the attacks. Her liver was enlarged and there was a slight icterus at the time of operation. Through a Sprengel incision the gall bladder was separated from the surrounding adhesions and removed in the usual way.

There was no pain during the operation and the patient made a smooth recovery.

CASE XI.—Intestinal Resection in Strangulated Hernia.—Frieda N., sixty-nine years old, was admitted to the First Surgical Service of Mount Sinai Hospital January 12, 1916. Twenty-four hours before admission, after taking a cathartic, she had had a sudden cutting pain in the hypogastrium, and a mass appeared on the left inguinal region. She had vomited three times, the pain had persisted, and she was unable to move her bowels. On admission a very tender swelling, the size of a hen's egg, was found in the left inguinal and femoral region. Attempts at reduction, both before and after admission to the hospital, proved ineffectual. I undertook the operation shortly after admission. On opening the sac it was found to contain some bloody fluid and a loop of necrotic small intestine. There was no pulsation in the mesentery, and to ascertain the viability of the gut the mesentery was cut at right angle to its vessels. The mesentery was incised 2 inches to one side of the necrotic gut and 4 inches to the other side before active bleeding was encountered. Ten inches of gut were removed, the ends of the gut crushed and ligated, and each stump buried with two rows of linen sutures. A typical side-to-side anastomosis with Connell linen sutures was done. The typical Bassini operation for femoral hernia was then carried out. The operation consumed one hour and fifteen minutes and had been preceded by a full dose of morphine. Novocain and adrenalin made the operation entirely painless, and at no time did the patient complain of any pain. She made an uneventful recovery. In view of her advanced years and the extensive operation that was necessary, a general anesthetic would have been associated with considerable danger.

CASE XII.—Radical Amputation of Breast for Carcinoma.—Fanny W., fifty-five years old, had been suffering from chronic nephritis for several years, with blood pressure of 200 and more. Two years before operation she had been in a hospital for an attack of uremia. She had had a tumor in her left breast for over six months before operation. A typical radical breast amputation was done through the Stewart incision. The axillary glands, both pectoral muscles, together with the entire breast and overlying skin, were removed in one piece. In other words, the technique was exactly the same as if the patient had been under ether. I first injected the apothesine around the upper half of the breast and cleaned out the axillary space at the beginning of the operation. I then injected the anesthetic around the lower half of the breast. The operation was quite painless and the skin was free from pain at the end of the operation, which took an hour. The microscopic diagnosis was scirrhus carcinoma. This patient, a very intelligent woman, assured me that at no time during the extensive dissection did she have much pain.

Multiple Operations.—In the following cases more than one operation was done at one sitting under local anesthesia:

	Cases.
Appendectomy and colpoperineorrhaphy	1
Double inguinal hernia	10
Appendectomy and excision varicose veins	1
Appendectomy and herniotomy	4
Umbilical hernia and hemorrhoids	1
Inguinal hernia and hemorrhoids	1
Cholecystectomy and choledochotomy	1
Appendectomy and salpingo-oophorectomy	1
Total	20

MORTALITY.

Private Cases.—Of the eighty-five cases there were two deaths:

CASE I.—A gentleman of seventy-three years, with an extensive carcinoma involving one vocal cord, had been under laryngological treatment for six months. I split the larynx, excised the tumor with one vocal cord, and touched the base with actual cautery. The operation was painless and was well tolerated. The patient had a comfortable night, but died very suddenly, presumably of an embolus, twenty-four hours after the operation.

CASE II.—A lady of sixty-eight years came to operation for strangulated umbilical hernia. There had been symptoms of intestinal obstruction, with rapid and thready pulse, for three days. The patient came to the operation in a desperate condition and died a few hours later.

Hospital Cases.—Of the 122 cases there were six deaths:

CASE I.—Acute appendicitis with abscess. The patient came to operation with an uncompensated valvular lesion and died of cardiac decompensation seven days after the operation.

CASE II.—Acute gangrenous appendicitis with peritonitis. This man had had diabetes several years. He died in diabetic coma eleven days after operation.

CASE III.—A man of sixty-five years had a suprapubic cystotomy done for enlarged prostate gland. He died of uremia in five days.

CASE IV.—An old man with extensive carcinoma of the larynx had had tracheotomy and excision of a specimen of the growth done by another surgeon. I did a hemilaryngectomy, which was followed by death in a few hours from shock.

CASE V.—A woman of fifty-six with inoperable carcinoma of the bile ducts died two days following an exploratory operation.

CASE VI.—Excision of large colloid goiter. Death ensued on the day after operation from shock or embolus.

In conclusion I think we are justified in saying that local anesthesia will save some lives, that it will eliminate ether pneumonia, and many of the other complications that we formerly thought were due to the operation, but now know are due to the anesthetic. It is particularly useful in peritonitis, nephritis, diabetes, arteriosclerosis, old age, and asthenia. But we are steadily widening its field and we hope in time, instead of seeking the indications for local anesthesia, we will rather question in every case the indications for ether. I feel that we have in this method a very valuable mine. We have but scratched the surface. Shall we dig deep down and unearth its priceless treasures?

41 East 78th Street.

FUTURE POLICY IN DEALING WITH DISABLED CIVILIANS; SOME CONCLUSIONS FROM EXPERIENCE.

By DOUGLAS C. McMURTRIE,

NEW YORK.

DIRECTOR, RED CROSS INSTITUTE FOR CRIPPLED AND DISABLED MEN, PRESIDENT, FEDERATION OF ASSOCIATIONS FOR CRIPPLES.

The rehabilitation for self-support of disabled soldiers and sailors has attracted wide public interest. As we now enter upon the reconstruction period there arises the question as to how far the policies developed in dealing with military cripples can be carried over for the benefit of disabled civilians. Some results have already been accomplished in the reeducation of industrial cripples. What conclusions helpful to the formation of future state or national policy have been drawn?

The first conclusion from experience is that rehabilitation of the disabled does not consist solely in vocational education. It is as largely a piece of social work as it is educational. The chief problem of any individual disabled man is a character problem. The chief necessity is to inspire his ambition, to overcome the tendency to inertia, combat the psychological conditions which inevitably develop with a permanent injury, and to inspire perseverance to continue the effort at rehabilitation when once begun.

Successfully to deal with the disabled men requires a special understanding of their difficulties and extraordinary patience on the part of directors, advisers, teachers, or social workers. The average disabled man, and particularly the civilian cripple, who enters on a course of training, is likely to abandon it in discouragement at the end of the first week. The average teacher who deals with him is likely to become disgusted before that time and be perfectly willing to let him abandon the course in the sure belief that the man is not worth bothering about. Yet those who have dealt with cripples understand that this is not the case, and that with the rule of "try, try again" success can be attained in the great majority of instances.

Although I heartily believe in the restoration of a disabled man to a place in the community as a normal being, rather than committing him to a special colony for cripples, I am convinced that the most effective agency of rehabilitation is a special school for the physically handicapped. In such a school every facility is designed for disabled pupils and all members of the staff are originally picked for aptitude in dealing with cripples, and their cumulative experience makes them more skilled in doing so. All the members of the staff of the Red Cross Institute testify that difficulties they considered insuperable in the first twenty men dealt with are now minimized by experience.

A special school for the disabled can have its own social service staff, an attending physician to keep watch on the condition of the men from the medical or surgical viewpoint, and a staff of teachers fully familiar with the special requirements of the work.

Foreign experience in rehabilitation seems to point most clearly to the need of special schools. Practically all the schools of reeducation in France have been organized for war cripples. In Great Britain, where the existing facilities of technical institutes have been largely availed of, it has been found in experience necessary to start special classes or sections for the disabled, as the men did not mix successfully with the regular pupils. Even in Canada, with the exception of the interesting placement in apprenticeship which has been done, the most successful reeducation has been in schools given over to become special institutions for disabled soldiers.

These considerations lead me to believe that miscellaneous introduction of disabled persons into a general system of vocational education would be unwise, but that the establishment of special institutions for the disabled would be most highly desirable.

The mere offer of vocational rehabilitation advantages does not by any means solve the problem of the idle disabled men, and it cannot safely be assumed that any considerable number of injured men in the United States will take advantage of rehabilitation opportunity, unless there is very radical readjustment of present state legislative provisions.

Our experience at the Red Cross Institute for Crippled and Disabled Men in New York very clearly illustrates this point. For over a year this school of re-education has been in operation. It offers a reasonable variety of subjects of instruction, six in all: mechanical drafting, moving-picture operating, oxyacetylene welding, printing, the making of artificial limbs, and jewelry work. All its advantages are free, yet it has at the present time less than forty pupils.

There are in New York City, however, according to statistics, thousands upon thousands of cripples who would profit by reeducation. What is the reason they do not take advantage of the opportunity?

The answer is found in the other influences upon the disabled man. The most potent of these is the

theory and practice of workmen's compensation. Practically every compensation case that has ever come to the Red Cross Institute has come upon the day compensation expired. For one year, for two years, or for four years, the man had existed in idleness, drawing compensation, and when this support was cut off he cast about and became interested in rehabilitation. When we come to examine the compensation provisions of the various States we find that they encourage idleness, in that the compensation payments are adversely affected by any improvement in earning capacity.

At a recent conference there was discussion of who should meet the cost of rehabilitating the disabled men. As far as the industrial cripple is concerned, so soon as the movement and its philosophy shall have gained some headway there should be no cost whatever. Merely by a reapportionment of funds already provided, effected through an understanding of the possibilities of rehabilitation, there will be a net cash saving rather than increase in expenditure. I can more clearly illustrate the possibility of this by statement of a typical case than by much theoretical elaboration. A worker in Massachusetts was injured by a fall while working inside a submarine, and his hand became permanently crippled. In due course his compensation rate was determined, and he was referred to the insurance carrier to be paid ten dollars a week for a long period, with a maximum total payment of four thousand dollars. Since the disability was manifestly permanent the insurance company wrote the case off their books as a four thousand dollar loss and transferred that amount to reserve to cover the weekly payments. After the compensation had been paid for nearly a year a new official of the insurance company began looking over the list of men to whom the company was paying compensation. His attention was directed to the man in question, and the latter was requested to call at the office of the company. The case was, like many thousands of others, susceptible of rehabilitation for self-support, so the insurance company official put a proposition to the man in very frank terms. "I believe that you can be trained to earn a good living. I want you to understand very clearly, however, that this proposal is to the financial advantage of the company, but I also believe it is to your advantage as well. A total income of ten dollars a week is not very attractive to you, and you would probably rather return to work at a good wage than remain idle. If you will consent, the company will send you to a school of reeducation and see if we cannot get you back on your feet in good shape."

The injured man consented to the proposal, and the company sent him to the Red Cross Institute in New York. They began to pay him not ten dollars a week as required by law, but forty dollars a week, twenty to him in New York and twenty to his wife at home. The company also paid liberally his traveling expenses in both directions. In the period of eight weeks he was reeducated in oxy-acetylene cutting and welding and returned home. He is now making not only a satisfactory wage, but twice as much as he had ever earned before the accident took place.

In the whole transaction every party at interest was benefited. The man was advantaged in that his general living standard was distinctly raised, and the necessity of working for his living could not be considered as a hardship. The company paid less than five hundred dollars for his rehabilitation, and this expense, in conjunction with the five hundred dollars already paid in weekly compensation during the first year of idleness, made a total for the case of one thousand dollars. They were thus enabled to charge three thousand dollars of profit to the account of profit and loss. Had the course of training been earlier begun, there would have been saved five hundred dollars more. The community was infinitely the gainer in that the man, formerly an unproductive consumer, became a useful producer instead. The community further gained in the elimination of the disabled man from the category of a prospective dependent, because while compensation might have taken care of him in a very insufficient way during the period the payments ran, there would have come a time when compensation ceased, and then he would have been in a desperate economic status indeed—confirmed in habits of idleness, untrained for skilled work, and without any source of support.

It is perfectly clear that if State compensation authorities will alter their practice so as to encourage rehabilitation rather than discourage it, if casualty insurance companies will see the path of true economy (and they are coming to this at the present time), there will be no cost in the rehabilitation of the industrial cripple but rather a great economic and social saving. The case just cited throws interesting light on the question raised as to whether future legislation should embrace in its scope accident cripples not under protection of workmen's compensation laws, congenital cases, and disease cripples. If any legislation is to be passed these classes should most emphatically be included because they constitute the cripples who are most in need of assistance. As has been shown, with developments which can confidently be expected within the next couple of years, the industrial cripple will not be in much need of financial assistance. It is the other cripples who contribute most largely to dependency and who involve the greatest community expense. Their restoration is desirable in the extreme, because the elimination of dependency due to physical handicap will lift a colossal burden from the agencies of philanthropic relief.

It has been already stated that rehabilitation is intimately related to workmen's compensation. So far as the industrial cripple is concerned the administration of rehabilitation should be coincident with that of compensation. It has not as yet been possible conservatively to draw definite conclusions regarding the exact provisions of compensation laws which should be altered. It seems clear, however, that one suggestion can come from the experience of all the belligerent nations in providing for the pensions of disabled soldiers. It has been evident from the first efforts at reeducation that pension must be paid for physical injury only and not be prejudiced by increase of earning capacity and subsequent restoration to self-support. Unless this provision is made it is almost impossible to persuade men to undertake re-education. A man does not like to lose one definite advantage, even though there is a greater advantage in store. All the mili-

tary pensions, therefore, are fixed, and a man may earn twice as much after his injury as before, and yet his pension will be paid to him just the same. On the other hand, we have learned that the scale of pensions is of comparatively little importance if adequate rehabilitation advantages are offered. In fact, a fairly low pension scale may be a means of character building and encouragement, whereas an extremely high pension scale may tend to demoralization and prove an encouragement to idleness.

It is possible, for instance, that in the field of workmen's compensation there may be a small statutory award for specific injury, and then be extended in addition opportunity of reeducation at the expense of the State fund or insurance carrier. If an earnest attempt at rehabilitation is made by the man, and for one reason or another he fails, there might then be a further discretionary award by the State compensation authority making the total payment as great or preferably greater than called for by the present scale. At any rate, the rehabilitation and compensation of industrial cripples are so intimately related as to be almost impossible of administrative division.

In rehabilitation of civilian cripples what are the financial circumstances involved? It is my belief that the cost of rehabilitation will average between two hundred and three hundred dollars per case, but this is, of course, highly economical, because when a man is rehabilitated his economic problem is solved for good and he is no longer a charge in any sense of the word.

The expense of rehabilitation will be apportioned about as follows:

	Per cent.
Salaries of administrative and teaching staff	20
Maintenance of pupils during training	50
Rent, or depreciation and interest on capital investment in building	10
Depreciation and interest on equipment	10
Supplies and material	10

You will note that maintenance is the large item. If you take the average cripple met on the streets and offer him the finest course of reeducation in the world, it is unlikely he will be able to take advantage of the opportunity. Though he is earning seven dollars a week, and there is prospect of increasing his income to thirty dollars weekly, it will be impossible for him to take the course offered, because he will starve meanwhile. This was one of the first lessons learned in starting out to rehabilitate disabled civilians. There is necessary for the average case some form of living allowance, and if the same governmental principle is to be applied to the crippled civilian as is now applied to the disabled soldier, this is properly a charge upon the rehabilitation organization. For the industrial cripple, of course, this maintenance may come out of compensation reserves if intelligent adjustment of practice and legislation is made, but for the general accident, disease, or congenital cripple, no such source of support is available. Any provision of rehabilitation would be, in the mind of the public, a failure unless maintenance were provided for.

In the table just presented there has not been taken into account the medical, social service, and follow-up attention which should likewise be encouraged.

Statistics show the number of disabled persons to be very great. Of course, a very large proportion of these men, particularly those with any character or initiative, readjust themselves industrially and get back in the work of the world in such a way that their employers hardly think of them as cripples. A large number can satisfactorily be put back into employment through provision of special and expert placement facilities. An essential link in the rahabilitation program is the provision of special placement bureaus for the disabled. The Red Cross Institute in New York has operated for the past year such a bureau, and has found that many men need only vocational guidance and intelligent search for a suitable job in order to have their problem solved. There has been already delegated to the United States Employment Service of the Department of Labor a vast placement enterprise. This service should be encouraged to develop in every large center of population a special bureau for the physically handicapped. Such placement work cannot satisfactorily be done through the ordinary public employment office, but when done carefully and thoroughly is certainly a public economy.

TYPHOID VACCINE AS A THERAPEUTIC AGENT.

By WILLIAM W. CADBURY, M.D.,
CANTON, CHINA.
OF THE CANTON CHRISTIAN COLLEGE.

The remarkable effects of intravenous injections of typhoid vaccine as a convenient form of foreign protein have been recently shown by a number of American writers. Engmann and McGarry[1] speak of the value of the use of typhoid vaccine in the treatment of cases of psoriasis, lupus, erythematosus, and other skin affections. Cecil[2] presents a careful analysis of 40 cases treated with the typhoid vaccine manufactured by the New York City Board of Health. His cases included acute arthritis, rheumatic fever, and gonorrheal arthritis. There were thirty-two per cent. of complete recoveries by this method and of the remaining all but two showed improvement.

Miller[3] reports the application of this treatment to both acute and chronic joint affections, and Thomas[4] gives an additional report on the same subject.

The conclusions of these observers show that in a large number of acute joint affections the injections of typhoid vaccine are entirely curative, while in the remainder, as well as in chronic affections, considerable relief may be expected by this form of therapy.

These favorable reports so impressed me that I decided to undertake the treatment on cases in my wards at the Canton Hospital. Since it was impossible to prepare fresh vaccines in our own laboratory I decided to use the commercial vaccines that were on the market. I found an old flask of Merck's streptococcus vaccine several years old and tried three or four injections of it, giving as much as 600,000,000 cocci in one intravenous injection. The substance proved to be inert. There was no reaction whatever. I then started to use typhoid-paratyphoid prophylactic vaccine as prepared by C. M.

TABLE OF CASES.

No.	Sex.	Age.	Diagnosis.	Complication.	No. of Injections.	Period of Injections.	Immediate Results.	Final Result and Remarks.
171025	M	20	Chronic arthritis	Gonorrhea, beriberi	5	16 days	Relief.	Cured. Pot. iodid. sod. salicyl. and mercury given without relief before vaccine was tried.
171432	F	33	Gonorrheal arthritis.	Leucorrhea.	5	18	Relief.	Much improved. Return of pain in one joint.
171434	F	20	Rheumatic fever.	High fever, 7 months duration.	6	24	Relief.	Improved. Tendency to relapse.
171522	M	30	Gonorrheal arthritis.		7	21	Relief.	Much improved. One joint remained swollen.
171565	F	17	Psoriasis.	Skin of soles of feet thickened.	5	12	Paler, less itching.	Recovered; all lesions cured but partial relapse in 3 months. Returned for treatment.
171614	F	57	Neuralgic pains of chest.	Inoperable cancer of breast.	5	11	Complete relief.	Improved. Vaccine more effective than morphine. Cancer appeared smaller.
171634	M	24	Gonorrheal arthritis.	Syphilis.	5	30	Relief.	Improved. Gonococcus phylacogen without effect. Last few injections of vaccine gave little relief.
187	M	20	Chronic arthritis.		1	1	Relief.	Left day after treatment saying he was well.
1836	F	17	Psoriasis.		2	4	Paler, less itching.	Improved. Left before cure was complete.
18142	F	19	Lichen planus.		6	15	Relief of itching.	Much improved. Nodules flattened, paler, no itching.
18150	F	42	Chronic arthritis.	Ankylosis of knee.	5	63	Relief.	Much improved. Patient able to walk.
18177	M	18	Psoriasis.		1	1	Relief.	Improved. All itching ceased after one injection.
18187	F	32	Chronic arthritis.	Right hip and knee.	4	15	Relief.	Improved. Ankylosis of joint. Pain relieved.
18432	F	40	Eczema, chronic.	Skin everywhere rough and thick.	4	12	Relief.	Recovered. Itching ceased.
18464	M	21	Chronic arthritis.	Rigidity of spine.	9	67	Relief.	Back unimproved. Temporary improvement of joints.
18481	F	16	Erythema induratum.	Mitral stenosis, syphilis.	2	8	Relief.	Cure.
18589	M	42	Neuralgia following gun shot wound.	Fracture of arm.	2	7	Relief.	Cure.
18637	M	46	Chronic arthritis.	Crepitus and ankylosis knees.	8	60	Relief.	Cure. No pain. Can walk.
18643	F	48	Neuralgia of chest.	Fibroid, phthisis and contraction of chest.	4	14	Relief.	Pains almost gone. Chest condition same.
18663	M	19	Chronic arthritis.	Knees flexed.	10	39	Relief after some injections.	Improved. Arms all right, some pain in knees.
18696	F	52	Chronic eczema.	Itching so severe cannot sleep.	2	5	Relief.	Cure.
18706	M	53	Chronic arthritis.	Rigidity of neck.	2	30	Relief.	Improved.
18711	F	29	Lichen planus.	Itching.	26	90	Relief.	Itching recurred between injections.
18760	F	40	Rheumatoid arthritis.		7	30	Relief.	Much improved.
18775	F	42	Chronic arthritis.	Right knee ankylosed.	3	13	Relief.	Much improved.
18777	M	30	Gonorrheal arthritis.		5	60	Relief.	Much improved.
18796	M	25	Neuralgia following gun shot wound.	Injury of spinal cord.	2	4	Relief.	Neuralgia pains cured.
18799	M	30	Neuralgia following gun shot wound	Bullet wound of shoulder and neck.	4	19	Relief.	Recovered.
18835	M	42	Chronic arthritis of hip.	Rigid hip joint.	5	23	Relief.	Improved; relief of rigidity and pain.
18843	M	..	Neuralgia following gunshot wound of thigh.	Much tenderness.	6	33	Relief.	Much improved.
18876	M	35	Chronic arthritis of hip.		1		Relief.	Much improved. Slight pain after two days.
18877	F	22	Tic douloureux.		5	10	Relief.	Some return of pain after two days.
18909	M	21	Chronic arthritis of hip and knee, etc.		8	50	Relief after first, 2 or 3 injections.	Slight improvement.
18957	M	38	Chronic arthritis hip and knees.		2	6	Relief	Improved.
18989	M	27	Gnnorrheal arthritis.		3	13	Relief.	Recovered.
181015	M	30	Chronic arthritis of knee.	Ankylosis.	4	5	Relief.	Recovered from pain, able to walk.
181048	M	42	Psoriasis.	Syphilis.	10	26	Relief of itching.	Recovered. After a month of syphilitic treatment there was no improvement.
Disp. 18 1083	M	2	Eczema of face and body.	Psoriasis.	11	90	Relief.	Relapse few days after injection.
181133	M	33	Neuralgia from perinephritic abscess.	Pains in leg and back.	1		Relief.	Refused operation because pain relieved by vaccine.
181134	F	36	Neuralgia of head, syphilitic.	Gumma of brain.	2	3	Relief.	Recovered after course of syphilitic treatment.
181146	F	31	Eczema of leg.		6	18	Relief.	Tended to relapse.
181151	M	56	Acute arthritis.		1		Relief.	Recovered.
181187	M	25	Acute arthritis.	Shoulder and knee.	5	14	Relief.	Recovered except for one joint.
181201	M	27	Neuralgia of neck.	Inoperable sarcoma.	1	..	No relief.	Ligature of carotid artery also without effect.
181210	M	27	Facial neuralgia.	Decayed teeth.	1	..	Relief.	Recovery followed extraction of bad teeth.
181215	F	21	Neuralgia from osteosarcoma.	Knee joint also affected.	3	7	Relief. Tumors smaller.	Operation later performed on tumors of hand and foot.
181282	M	16	Chronic arthritis.		1	..	Relief.	Refused further treatment.
181285	F	26	Acute arthritis.	Malaria.	2	7	Relief.	Cure.
Disp. 181618	M	36	Syphilitic arthritis.		1	..	Relief.	Had novarsenobenzol, but relief greater after use of vaccine.
CCC A	M	31	Psoriasis.		5	10	Relief of itching.	Cure. Relapse in three months.
CCC B	M	..	Acute arthritis.		1	..	Relief.	Recovery.

Heanley of Hongkong. This was given within the time limit marked on the cover, and caused a marked reaction. Finally Burroughs and Wellcome of Shanghai kindly offered to supply me, free of cost, typhoid vaccine which had passed the date marked on the cover. One batch was labeled "not to be used after Dec. 25, 1917," and this was used after Jan. 1, 1918. The other batch, which was marked to be used before May, 1918, was given in June or thereafter. In our experience the fresh and the old typhoid vaccine are equally effective even though the latter be injected as late as six months after the date marked on the cover.

The solution for injection was prepared by mix-

ing the contents of an ampul of typhoid vaccine with sterile normal saline solution in such proportion that 1 mil should contain 100,000,000 of the bacilli. This was then kept in a sterile glass bottle and used as occasion demanded. There seemed to be no deterioration even after a week. In an adult the initial dose given was sixty to seventy million bacilli, increasing the quantity by ten million in each injection till as many as 100,000,000 were injected at a dose. An ordinary hypodermic needle was employed and the solution was injected in a vein at the bend of the elbow or forearm or hand or, in infants, in the external jugular vein. In the fifty-four cases that were treated we did not find a single one in which it was not possible to make the injection without cutting down on the vein. After the injection there was no local reaction at all. A chill usually followed in about one-half to one hour, followed by fever which persisted for from four to twelve hours, causing headache and malaise. In a few instances fever persisted for a day or two. There were no untoward symptoms although one or two patients complained of considerable distress. One case, a girl with a mitral stenotic murmur, had considerable palpitation with tachycardia. In general it may be said that patients with organic heart disease stand the vaccine injections less well. Altogether more than 200 injections have been given and in no case would we feel unwarranted to repeat if symptoms called for it.

Injections were usually given every third or fourth day and not then if there was any fever persisting after the last injection. In some of the cases injections were given only when there was a recurrence of symptoms, once a week or even at longer intervals.

I desire to express my appreciation to my colleague, Dr. J. M. Wright, who referred several of the cases to me for treatment and offered valuable suggestions in carrying out the work. After the treatment had been thoroughly inaugurated most of the injections were given by my hospital internes, Drs. Chiu Lok Nin, Wong Min, and Wong Uen Hing.

It has been impossible to follow up most of the cases after they left the hospital so that the results recorded are generally those noted when the patient was discharged from the hospital. Two of the cases were members of the teaching staff of the Canton Christian College, two were out-patients at the Canton Hospital, and all the others were admitted to the wards of the Canton Hospital. All were Chinese except one, who was an American.

Perhaps the chief evidence in favor of this treatment came from the patients themselves, who, in spite of the temporary discomfort caused by the reaction, seldom objected to subsequent treatments and often begged the physicians to give the next one before it was due.

We shall now consider the various conditions which were treated with the vaccine injections. They may be summerized as follows: Acute arthritis, 4 cases; Rheumatic fever, 1; Chronic arthritis, 16; Gonorrheal arthritis, 5; Syphilitic arthritis, 1; Neuralgia, 11; Tic douloureux, 1; Psoriasis, 5; Lichen planus, 2; Eczema, 4; Erythema induratum, 1.

Acute Arthritis.—There were 4 cases diagnosed acute arthritis Nos. 181,151, 181,187, 181,285, and C.C.C.,B. Three were male and one female. One was complicated with malaria. In one the phalangeal joints were affected. Salicylates were given with some benefit, but complete relief followed one injection of vaccine. In another the shoulder joints and one knee were painful. Sodium salicylate and aspirin gave some relief, but after 5 injections of vaccine the knee and one shoulder were free from pain, but one shoulder joint remained unimproved. The other 2 cases were completely relieved by doses of vaccine.

While in these cases salicylates were given in addition to the vaccine their usefulness seemed to be limited to a certain degree of improvement only, the injection of vaccine was followed in a few hours by marked relief and seemed to be the chief factor in bringing about a complete cure.

Rheumatic Fever.—Only one case, No. 171,434, was treated, a young girl with heart complications and a septic temperature. Each injection was followed by marked relief of pains, but the condition relapsed each time. The patient had been sick for 7 months and left the hospital against advice, before she was completely cured.

Chronic Arthritis.—Sixteen cases diagnosed as chronic arthritis were treated with the vaccine, viz., Nos. 171,025, 187, 18,150, 18,187, 18,464, 18,637, 18,663, 18,706, 18,760, 18,775, 18,835, 18,876, 18,909, 18,957, 181,015, 181,282. Of these, 4 were female and 12 male. Two gave a history of syphilis, and 3 of gonorrhea, although in neither case did these diseases seem to be causative factors of the arthritis. In 3 cases only one joint was affected, the knee in 2 and the hip in 1. In 13 cases 2 or more joints were involved, 4 of the patients were given potassium iodide, and 9 had some salicylate preparation. The benefit from these drugs was only partial, but the immediate relief afforded by the vaccine injections seemed to indicate its influence on the final result. Two cases were discharged cured, seven were very much improved and seven showed some improvement. In every case the initial injection of vaccine gave marked temporary relief. Several patients with stiff or ankylosed joints required chloroform anesthesia to break up the adhesions. The pain, however, was relieved by the vaccine. The following history, 18,760, is typical.

Mrs. M., history of repeated attacks of rheumatism. Four years ago was greatly benefited by rheumatism phylacogen, but relapsed in 2 months. Went to Battle Creek Sanitarium, and recovered after about 3½ months. Relapse about 5 months ago. Examination shows swelling and severe tenderness of toes, knees, wrists, and fingers. Had been taking potassium iodide and sodium salicylate and aspirin with only slight improvement. After 7 injections of vaccine, followed by immediate temporary relief, patient felt almost entirely free from pains. She reports the treatment much less painful and more effective than that with rheumatism phylacogen.

Gonorrheal Arthritis.—Under this heading there are five cases that were treated with typhoid vaccine, Nos. 171,432, 171,522, 171,634, 18,777, 18,989. Only one of these was a female. In all but one more than one joint was involved. In all cases there was immediate relief following the injections. One was considered cured and the other 4 much im-

proved. In several only the first 3 or 4 injections gave relief; subsequent doses gave little benefit. In one gonorrheal phylacogen was given without immediate relief, but the vaccine caused all symptoms to improve.

Case No. 171,522.—Male, age 30. Had a chancre 3 years ago, but no skin eruption. In July, 1917, had gonorrhea, and 10 days later developed pains in right heel, both knee joints, and 2 months later upper limbs and back were affected. Received 50 million bacilli on Dec. 30, 75 million on Jan. 7; on the 8th noted very marked relief in all joints except one knee. On the 12th and 15th two more injections without much change in knee. Further injections on 19th, 22d and 24th. Left hospital about well except for some pain persisting in the left knee. Sodium salicylate was given beginning on the 17th and potassium iodide on the 21st, but these caused no evident improvement.

Syphilitic Arthritis.—Case Disp. No. 181,618. Patient gave a history of syphilis and desired to have treatment with novarsenobenzol. Three doses were given, but pain still persisted in knee joints. The Wassermann test proving to be negative, 2 injections of vaccine were given with marked relief of all symptoms.

Neuralgias.—There were 11 of these cases, Nos. 171,614, 18,589, 18,643, 18,796, 18,799, 18,843, 181,133, 181,134, 181,201, 181,210, 181,215. The first was a patient with inoperable cancer of the breast, who suffered intense pains which nothing seemed to alleviate. After the dose of vaccine the patient slept like a child. The pain recurred and ultimately the vaccine lost its effectiveness. Nos. 18,589, 18,796, 18,799, 18,843 were all men with gunshot injuries involving nerves. After healing of the wounds neuralgic pains persisted, requiring morphine to alleviate them. Vaccine injections brought rapid and permanent relief.

No. 18,463 was a case of neuralgia of chest due to fibroid phthisis. In No. 181,133 the pains were due to pressure of a perinephritic abscess, and in 181,215 from osteosarcomata. In all these the pain was greatly relieved. No. 181,201 had one injection of vaccine to relieve the severe pain from an inoperable sarcoma of the neck. No relief was afforded. In 181,210 decayed teeth were found to be the cause of facial neuralgia. Before the teeth were extracted considerable relief was given by an injection of vaccine. No. 181,134 was a case of headache due to gumma. Vaccine was given by mistake before syphilitic treatment was started. The headache was considerably relieved; appropriate syphilitic treatment ultimately produced a cure.

Tic Douloureux.—The most severe case of neuralgia was No. 18,877, suffering with tic douloureux. This girl of 22 had suffered for more than a year. The paroxysms came every 10 minutes and the patient would seize her head in her hands. Five injections of vaccine were given in 10 days. For 24 hours after there was complete relief of all pains; after this slight headache began to appear. Patient left the hospital after the last treatment so that the final result is unknown.

Psoriasis.—Nos. 171,565, 1,836, 18,177, 181,048, and C.C.C.A. were all pronounced cases of psoriasis, and in no affection is the result of vaccine more striking. As a rule 2 or 3 injections are given, with a marked relief of itching and fading of lesions, and the cure is greatly hastened by the application of a weak chrysarobin ointment 2 to 4 per cent. All of the cases were temporarily relieved, but relapse occurred sooner or later.

Case C.C.C.A. is typical. Male, age 31, teacher. Has suffered from psoriasis since 6 years of age. Worst on face and scalp. Back and limbs also affected. Always worse in the winter but never entirely well. Has been treated by both Chinese and Western doctors with little improvement. Jan. 5 gave first treatment when condition was at its worst; subsequent injections given on 7th, 9th, 12th, and 15th. Lesions began to fade and itching decreased after second injection, on Jan. 9th; 3 per cent. chrysarobin ointment was given, which caused a slight dermatitis and was discontinued on 15th. On Jan. 22 all lesions had completely healed except a very small spot on the leg. One month after last injection there was some return and in 2 months there are several patches again on the skin.

Lichen Planus.—Cases Nos. 18,142 and 18,711 were diagnosed as lichen planus. There was considerable itching with elevated purplish areas. In both the elevated areas became flattened and disappeared, and the itching was greatly relieved though there was return of itching later.

Eczema.—Cases Nos. 18,432, 18,696, Disp. 181,083, and 181,146. Three of these patients were adults with chronic dry eczema. Vaccine caused marked temporary relief, but the itching recurred in 2 or 3 days. The other case was that of an infant whose face was covered with a moist eczema. The body also was greatly involved. Injections caused a slight temporary improvement only.

Erythema Induratum.—Case No. 18,481 had hard painful nodules on limbs. Various forms of treatment were tried without avail, but after 2 injections of vaccine the indurated areas rapidly healed and there was no recurrence.

Conclusions.—1. Commercial typhoid, or typhoid-paratyphoid vaccine, prepared for prophylactic inoculations, has unique and very marked therapeutic properties if injected intravenously.

2. This vaccine appears to lose none of its therapeutic efficacy if diluted with saline solution, or if given as much as six months after the date of expiration marked on the container.

3. In acute arthritis, associated with little or no fever, injections of vaccine will generally complete a cure, only partially accomplished by salicylates, aspirin, etc.

4. In rheumatic fever temporary amelioration of symptoms, at least, may be expected by the use of vaccine treatment.

5. In chronic arthritis, whether it be rheumatoid arthritis, or chronic monarticular affections, the pain is always temporarily and usually permanently relieved, and swelling and crepitus in joints may be greatly decreased. In these chronic conditions the vaccine alone is not sufficient to complete a cure but is a most valuable adjunct to other well known measures, such as the use of salicylates, baking, electricity, massage, etc.

6. In gonorrheal arthritis typhoid vaccine appears to be as effective as gonorrheal vaccine, and in conjunction with other measures is a valuable addition to our therapeutic armamentarium.

7. In syphilitic affections typhoid vaccine is effective in relieving pain, though not in any sense equal to the recognized antisyphilitic remedies.

8. In various forms of neuralgic pain, otherwise only to be relieved by morphine, typhoid vaccine is most effectual, *e. g.*, the pains of carcinoma or sarcoma, and the pains following gunshot wounds with

injury of nerves. Not only is the pain temporarily relieved, but it may be permanently checked after 2 or more injections.

9. In tic douloureux typhoid vaccine may act far more effectively than morphine.

10. Psoriasis can be temporarily cured by the vaccine.

11. Lichen planus can be temporarily cured by vaccine.

12. The itching of eczema may be temporarily greatly relieved by vaccine.

13. Erythema induratum may be cured by the vaccine.

MILITARY ORGANIZATION AND THE TREATMENT OF THE TUBERCULOUS SOLDIER.

By OWEN PAGET, M.D., Captain Australian Army

Monte Video Camp (Australia), Weymouth, England.

This paper compiled from observations on nearly 300 tuberculous and query tuberculous soldiers is intended to give an impression of the practical application of my theories on the treatment of tuberculosis under military conditions.

To those who are not acquainted with my papers on tuberculosis published in America and Australia, it may suffice to state briefly that the surface epithelial cells of the ethmoid, superior and middle turbinates, and nasal sinuses are capable of forming antibodies against tuberculosis. This action is brought into play by insufflating powders of an emulsion of dead tubercle bacilli, known as tuberculin B. E. onto these surfaces by means of a glass tube and a Politzer bag. The tuberculous and query tuberculous cases here of which I have sole charge number about 130 when the wards are full. They are congregated in a hutted hospital within a depot camp.

One sister is in charge of two or three wards, and they have only hospital orderlies to assist them. There is, therefore, no constant supervision of the patients, who unless seriously ill are allowed complete freedom. After the first week here leave is granted to visit the neighboring town daily from 2 to 9 p. m.

Patients with temperatures over 100° are not supposed to leave the wards to go to the latrines. The use of drugs except a little digitalis for heart conditions, is almost nil.

The diet is on a liberal scale, but forced feeding is not employed. The wards are airy, but smoking is permitted, and no particular rules are laid down as to ventilation.

From this it will be seen that my treatment has not been materially assisted by other means. There is, however, a natural tendency to improvement here in the first 14 days, without the employment of any remedy.

Classification.—The cases are divided into tuberculous (positive) and query tuberculous. The tuberculous are again divided into tuberculous (bacteriological) and tuberculous (clinical).

The former class immensely predominates, as the consultants are reluctant to classify as tuberculous any case which does not show positive evidence in the sputum.

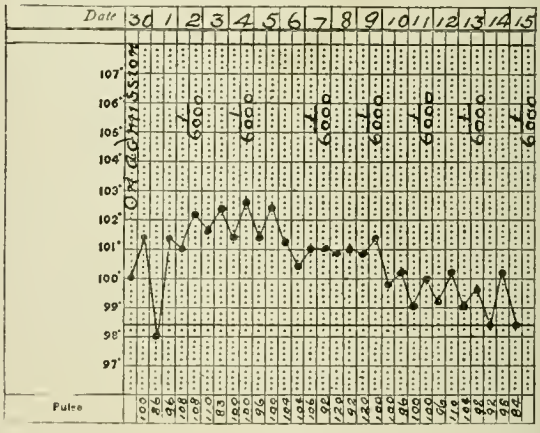
The query tuberculous, after 3 sputum tests extending over about 14 days, ultimately become either positive tuberculous or are listed bronchitis, fibrosis of lung, emphysema, etc., according to the consultant's finding.

Cases classified as tuberculous remain here till embarkation for Australia.

Routine Treatment.—The first two days after admission the patient is kept in bed to ascertain his real condition. Camp leave is allowed only in the first week.

Treatment which is not arbitrary, but guided by the personal equation of the patient, is usually commenced on the third day, and consists of an insufflation of 1/6000 mgm. of bacillary emulsion. This is given every second day up to six doses. If the temperature is now near the normal line, the dose is increased to 1/500 mgm. for six doses, and then increased to 1/40 mgm.

The method of insufflations has been described in previous papers. They are administered by an A. M. C. corporal.



A percentage of cases show, on admission here, as a result of traveling, a temperature of 101° to 102°. This usually quickly subsides under treatment. Other cases, even after treatment has commenced, will, during the first week or so, develop a typical pneumonia or pleurisy. Treatment in these cases, as well as in severe hectic cases, is continued on exactly the same lines with insufflations, but the dose is not increased over 1/6000, until the temperature has remained some four or five days at normal. The temperature falls to normal usually by lysis in approximately 10 days. The temperature once down does not tend to rise again. The attack is obviously modified so far as general symptoms and physical signs are concerned, but the temperature is apparently not immediately affected. The accompanying chart is a good example of the results of treatment in so far as the temperature is concerned. This patient had a definite pneumonia of his left lung. Duration of ill health about 2 years.

Treatment is carried on even with hemoptysis, and now I employ no other procedure in this condition. With the partial exception of a very ad-

vanced case with extensive mischief and with perforation of the nasal septum, in which proper insufflation has been very difficult, every case of tuberculosis treated has made positive and consistent progress to recovery. There have been no misfires, and only one or two cases have shown any lagging in their progress. Probably these were cases in which I underestimated the virulence of the disease as shown by the physical signs, with the result that they were too quickly pushed on to the maximum dose.

Breathing exercises are for two reasons of great importance after convalescence is established. They are usually started about six weeks from the commencement of the treatment. It is, first of all, important to test whether the patient is in a condition of stable or unstable equilibrium in so far as his disease is concerned. Mere quiescence does not necessarily imply either real healing or recovery. By graduated exercises to the lungs it is possible to test the liability to recurrence. So far this has been negligible. If a rise of temperature occurs, breathing exercises are suspended for a few days, to be resumed as speedily as possible.

The second reason for the use of breathing exercises is that the symptom which lasts longest is weak breath sounds, especially noticeable at the bases. The lung in the tuberculous patient is like an injured limb, instinctively kept as much as possible at rest.

In limb surgery the mere healing of a wound no longer suffices us, and the patient is passed on for orthopedic treatment to restore full function to the injured part. In tuberculosis the reexpansion of the lung is equally important.

The period of time for treatment here before embarkation is roughly speaking about two to three months. Our procedure is now routined, and we expect and are getting good results. The intention, hope, and aim of the system is to land the Australian tuberculous back into his own country in as good health as on the day of his enlistment. Failing this we consider it possible to achieve as good results in the healing of these tuberculous cases, as the surgeons and orthopedists obtain in their particular sphere.

To thank individually all to whom I am indebted is impossible. Few believed, yet all have helped me.

GROPING IN MEDICINE.

BY BEVERLEY ROBINSON, M.D.,
NEW YORK.

PERHAPS, feeling one's way, would be better and more explanatory. At all events, to some it would seem pleasanter to the ears, as showing something like rational trial and research, or evidence from facts, when acquired. Empiricism, so termed, is in this line, and, alas, so is much to-day that is called experimental science, based upon laboratory research and essentially attached to the history, development, and behavior of microbes—the bugbear of the younger generation of physicians.

The thoughts that arise in my mind are suggested and furthered by the attitude of many of our guides to-day *in re* influenza and its treatment. Because we have no specific against it, because we cannot as yet stop its advent and wide dissemination, because we cannot cure it indubitably when it occurs, why do much, or anything, in a preventive, or remedial way, until we shall have surely found a vaccine or serum that will do the job and indeed, one or another, upon which all the experts shall be of one mind as to its absolute safety and reliability?

The truth is, from a broad and sane viewpoint, we do know certain things about as well as they will probably be known in the years to come. We know what our forebears for many generations believed advisedly and thoroughly, and much of this is still good and true and should claim our abiding and unalterable faith. Others are now and were *sub judice*, but should at least have our respectful indulgence as to their merits. I claim even now that Huxham's tincture of bark, the formula of which is over one hundred years old, will still cure, or greatly ameliorate, in most instances, not only malarial fever, but also many febrile conditions of uncertain or unknown provenance.

I claim that since my boyhood days I know of no combined remedies that will soothe, quiet, and help beneficially a patient in many acute ills more than the sweet spirit of nitre and the spirit of mindererus. In an acute cold, when the nose is stopped up, when there are chilly and febrile conditions, a mustard footbath and a hot toddy at bedtime, with or without a Dover's powder, will do the trick when the coal tar products of latter years are prejudical or worthless. And as to vaccines, or serums, they had far better be left wisely alone, at least for the while. After numerous trials of many remedies and treatments, throughout a long series of years, I have concluded that in salicylate of ammonium I have found the best remedy, preventive and curative, of ordinary colds and also of influenza. It will not prevent or cure all cases, and I know of absolutely nothing that will, but it will be, of all remedies, the least objectionable or harmful. Of course, there are personal peculiarities that should always be considered with remedies, as with foods. Just as eggs are poisonous to a few people, so may salicylate of ammonium be. In moderate, frequently repeated doses, I have yet to meet any one that was affected in an alarming way. I have met some whose stomachs or ears could not tolerate the salt for long. In regard to the precise dose for any one, I cannot prejudge, and must rely upon

feeling one's way. I already know that, for many, five grains of salicylate of ammonium in a capsule at the beginning of a cold and taken every hour, for five, six, or even ten or twelve doses, is none too much. Thus taken, a beginning cold or influenza may be practically aborted, in some instances, in twenty-four hours.

Alas, there were instances, and not a few, in our late epidemic of influenza, in which this, like all remedies, failed. But, is not this true in certain cases of every threatening acute disease and of all remedies yet acquired by our profession through all its long ministry to human ailments? The best, the most learned, the wisest practitioner of medicine, must grope, must feel his way, must often make repeated, intelligent trials before he hits upon the real thing. And even this real thing will go back upon him when he least expects it and when previously he was most hopeful, and then something which he had not hitherto tried in what seemingly was a like case, simply does the work admirably; that is, it relieves or cures the suffering one.

A final thought is this: Every man's experience is his own, not another's. All he can do, therefore, is to report truthfully and advisedly his own findings, trusting to the future and to his fellows to mark what is good and useful and to ignore or pass over what does not fill the bill.

Rectitude in one's statements is what we most want, and if it forms the basis for one's convictions, we must trust the latter until multiplied counter evidence cancels them.

10 West Thirty-seventh Street.

Medicolegal Notes.

Discussion of Liability of Charitable Hospitals.—There is a great diversity of opinion among the courts on the question of the liability of a charitable institution to respond in damages for negligence. Some courts hold it is not liable at all for negligence. Other courts hold, though liable to others, it is not liable to a patient received for treatment, when the injury resulted from the negligence of employees and servants. Some courts hold that, though not liable at all for the negligence of its servants or employees, it is liable for injuries traceable to some negligence on the part of the corporation itself; a failure to discharge some duty that cannot be delegated to servants to perform. Thus an exception is made where the liability is traceable, not to the negligence of servants, but to the negligence of the defendant in employing incompetent servants. Even where liability has been found, the courts have based their holdings upon entirely different reasoning. Some say there is no liability because trust funds cannot be diverted from trust purposes to the satisfaction of claims for negligence. Others courts repudiate this doctrine that the funds are in the nature of trust funds and cannot be diverted from their purpose, and hold such an institution liable to a stranger or a servant for negligence, though not liable to a patient on the theory of an implied contract not to hold the institution liable for the manner of the treatment by its servants. In some cases they have been exempted from liability because they are considered agencies of the government. The Iowa Supreme Court thinks the great weight of authority is to the effect that an institution of this kind is exempted from liability to one who comes to it and accepts the benefit of its charity, to a patient received for treatment, so far as liability is predicated on the negligence of its servants in administering the charity. It therefore holds that a hospital whose purpose is not to pay pecuniary profits, being supported by donations and charges against patients able to pay, is not liable for the negligence of its servants to a pay patient. Assuming that a charitable hospital is liable for its negligence in furnishing incompetent nurses, it holds that it must affirmatively appear that an injury complained of was caused by lack of reasonable care in the selection of the nurses, and not to the independent negligence of such nurses.—Mikota v. Sisters of Mercy, Iowa Supreme Court, 168 N. W. 219. The California District Court of Appeals holds that a hospital not run for profit, and which in fact did not make any profits, was not liable to a pay patient for negligence of its employees (in this case nurses), where no negligence was shown in the employment of incompetent employees. The court followed the rule laid down by the California Supreme Court as follows: "Where one accepts the benefit of a public or private charity he exempts by implied contract the benefactor from liability for the negligence of the servants in administering the charity, if the benefactor has used due care in the selection of those servants." The court said: "The fact that plaintiff paid the regular rates charged by the hospital for paying patients does not take the case out of the operation of this rule, for it is apparent that the rates were not charged with a view of making a profit from her, and the moneys received from paying patients were not in fact sufficient to meet even the ordinary operating expenses of the hospital, without considering any interest upon the amount invested in the buildings. It is clear, therefore, that plaintiff was to some extent the beneficiary of the charity for which defendant corporation was organized, and comes within the rule quoted."—Burdell v. St. Luke's Hospital, 173 Pac. 1008.

Meaning of "Infection" in Accident Policy.—Action was brought upon a policy insuring from "accidental bodily injuries." The assured struck her leg against a truck in the department store where she worked, causing an abrasion, which became infected by the germ staphyloccus, from which developed acute general septicemia, resulting in her death. The policy contained a clause limiting the insurer's liability by 10 per cent. where the injury or loss results from, or is contributed to, by any poison, disease, infection, asphyxiation, gas, hernia, fits, vertigo, etc. The trial court construed this limitation to apply to and cover an infection received with or in consequence of the injury and as a part thereof. The New York Appellate Division thinks it should not be so construed, and that the limitation applies only to a poison, disease or infection from which the deceased was suffering prior to and at the time of the accident. Farniane v. Standard Acc. Ins. Co., 171 N. Y. Supp. 1018.

Evidence as to Infection in Personal Injury Cases.—The opinions of medical experts are essential in a personal injury action for the guidance of a jury as to infections, their causes and progress, as such matters left to the guesses of the uninformed would make possible damages based solely on speculation, and not upon evidence. The Illinois Appellate Court holds that the opinions of expert medical witnesses as to the character of the infection of the breast of a woman who was injured in a street car accident, as the result of her child being thrown against her while in the act of alighting from a car, and as to the possibility of infection either with or without any blow, are neutralized in effect where their opinions as to the causal connection are predicated upon the absence of any prior injury.—Rose v. Chicago City R. Co., 207 Ill. App., 345.

Dying Declarations.—It is not necessary to entitle a statement to be admitted in evidence as a dying declaration that the deceased should have unequivocally stated he was about to die, or that he realized his death was impending. Any act or expression which clearly shows that the deceased realizes the seriousness of the situation, and that he is in extremis is sufficient. Measured by this rule, the statements of the deceased in a murder case that she felt that she must die, and later called for a priest to administer the last rites and to anoint her, she being a member of the Catholic Church, clearly indicated that she visualized the situation, realizing that death was impending. Her statement afterward made that her husband gave her paris green for her bowels was held properly admitted as her dying declaration.—Ulrich v. Commonwealth, Kentucky Court of Appeals, 205 S. W., 586.

Military Medicine.

Doctors Needed in Siberia.—A despatch from Dr. Arthur Rudolph Teusler, head of the Czechoslovak Medical Service, to the *Associated Press*, states that there is urgent need of doctors, nurses, and medical supplies in western Siberia. The spread of typhus and the coming of 200,000 Russian soldiers, formerly imprisoned in Austria and Germany, are imposing a heavy burden on the military service. Dr. Teusler has directed the establishment of Red Cross hospitals at Omsk, Ekaterinburg, Cheliabinsk, and Tiumen. At Ekaterinburg the public bathhouse has been transformed into a typhus hospital.

Two American Units End Hospital Work in France.—The American Military Hospital No. 1, at Neuilly, near Paris, announces that its work has been completed, and no more funds will be raised. This is the hospital first organized under Dr. Joseph A. Blake, formerly of New York, and was known as the Ambulance Hospital. During the war more than $2,000,000 has been contributed to the maintenance of this hospital by the American committee. After the battle of Chateau-Thierry the capacity of the hospital was expanded from 575 beds to 2,000, and for an extended period from 600 to 800 new cases were received daily. In bringing its labors to a close the American committee feels a pardonable pride in the achievements of this hospital. It provided for the wounded the best medical, surgical, and nursing care, and made a notably high record of lives saved and of men restored to health.

The Yale Hospital Unit has also completed its work in France, and sailed for this country on January 16. This unit is under the command of Lieutenant Colonel Joseph M. Flint.

Sick Soldiers to be Sent South.—In an official announcement, under date of January 13, Surgeon-General Ireland directs that soldiers suffering from respiratory diseases be transferred to Southern hospitals. All those who have severe and persistent bronchial symptoms, and whose recovery in Northern hospitals is likely to be slow, will be transferred.

Red Cross Aids Women's Hospitals.—The Red Cross has given $50,000 to the American Women's Hospital Association for the maintenance of its Hospital No. 1, at Luzancy, France. This hospital is cooperating with the American Committee for Devastated France.

Dr. Harold Hayes has returned from active service in France and has resumed his practice at 2178 Broadway, New York City.

Deaths in the Service.—Major Asa Charles McCurdy, M. C., U. S. Army, of Battle Creek, Mich., a graduate of the University of Michigan, Ann Arbor, in 1908, attached to the Fifty-second Engineers, died in Brest, France, on November 28, from the effects of a carbuncle on the face, at the age of 32 years.

Lieut. Reese Davis, M. C., U. S. Army, of Forest City, Pa., a graduate of Jefferson Medical College, in 1916, aged 25 years, died in France from wounds received in action, on September 27.

Capt. William Chester Smith, M. C., U. S. Army, of Chicago, a graduate of the University of Louisville, Ky., in 1904, and of the University of Illinois in 1913, died of valvular heart disease while on duty at Camp Sherman, Chillicothe, Ohio, on December 11, aged 38 years.

Lieut. Homer Joseph Slocum, M. C., U. S. Army, of Carrollton, Ky., a graduate of the Louisville, Ky., Medical College in 1903, died from pneumonia, following influenza, while on duty at Camp Greenleaf, Fort Oglethorpe, Ga., on October 17, aged 39 years.

Capt. William George Turner, M. C., U. S. Army, of Fall River, Mass., a graduate of the Baltimore Medical College, in 1904, died from pneumonia, following influenza, while on duty at Fort Benjamin Harrison, Ind., on October 11, aged 39 years.

Lieut. Edwin Franklin Syrop, M. C., U. S. Army, of Bayonne, N. J., a graduate of the University of Maryland, Baltimore, in 1916, died from lobar pneumonia in Base Hospital No. 78, France, on October 27, aged 28 years.

Capt. George H. Hockett, M. C., U. S. Army, of Anderson, Ind., a graduate of the College of Medicine and Surgery, Chicago, in 1910, who entered the Officers' Training Camp at Fort Benjamin Harrison, Ind., served at Fort Oglethorpe, Ga., then went overseas in charge of the Three Hundred and Thirty-fourth Sanitary Train, Fourth Division, and participated in the fighting at Chateau Thierry, Soissons, Cambrai, and Argonne Forest, died of heart disease on December 1, aged 35 years.

Capt. John Van Doren Bedinger, M. C., U. S. Army, of Anchorage, Ky., a graduate of Johns Hopkins University, in 1911, aged 32 years, died from pneumonia, in Liverpool, England, on October 20. He was associate professor of pediatrics in the University of Louisville from 1913 to 1917, and served at Camp Oglethorpe, Ga., and Camp Shelby, Hattiesburg, Miss., before going abroad.

Lieut. William Adam Lieser, M. C., U. S. Army, of Celina, Ohio, formerly of Fort Recovery, Ohio, a graduate of the Eclectic Medical Institute, Cincinnati, in 1914, aged 34 years, is reported to have died recently in France from wounds received in action.

Major Emile L. DeLanney, M. C., U. S. Army, of Omaha, a graduate of the John A. Creighton Medical College, Omaha, in 1901, chief of the medical service at Fort Des Moines, Iowa, died in the post hospital at Des Moines, December 23, from influenza, aged 46 years.

Lieut. Wilford Andrew Fair, M. C., U. S. Army, of Pleasant Hill, Mo., a graduate of the University Medical College of Kansas City, Mo., in 1909, aged 35 years, was killed in France on October 6, during the fight in the Argonne Forest, while attempting to aid a brother officer who was wounded.

Lieut. Ralph Thomas Saunders, M. C., U. S. Army, of Sandusky, Ohio, a graduate of the Ohio State University, Columbus, in 1917, died in Camp Eustis, Va., on October 11, from pneumonia, following influenza, aged 25 years.

Major Harrison Briggs Webster, M. C., U. S. Army, of Castine, Me., a graduate of Harvard Medical School, in 1909, aged 34 years, was killed in action in France on October 12.

Lieut. Davis King Summers, M. C., U. S. Army, of Chattanooga, Tenn., a graduate of Emory University, Atlanta, Ga., in 1915, aged 30 years, was killed in battle in France, on March 1, 1918.

THE ABNORMAL FORMS OF CEREBROSPINAL MENINGITIS.

THE anomalous forms of cerebrospinal meningitis consist either in a predominance of the morbid process in some other system (pulmonary, circulatory, genitourinary, nervous) or in the gravity of the symptoms or the rapidity of the evolution.

The pulmonary type of the disease has been described by many competent writers, and is more frequent than is generally supposed. Epidemic foci have been referred to in which pulmonary localizations of the meningococcus were more common than meningeal. The lesions usually met with are pulmonary congestion, bronchitis, bronchopneumonia, and lung abscess. Serofibrinous pleurisy has been observed either at the beginning of the disease, at its full development, or during convalescence.

The heart is less frequently the seat of the process, but a number of writers have observed a pericardial fluid collection due to the specific organism. Lesions of the myocardium have been described, and in one instance an abscess was found.

The urogenital localizations of the meningococcus are of great interest on account of the similarity between the specific organism of cerebrospinal meningitis and the gonococcus, rendering the diagnosis a matter of some difficulty, and the development of meningeal symptoms may alone clear up the true situation. Suppurating cystitis due to the meningococcus is more frequently observed in babies. In adults, albuminuria seems to be the only meningococcal manifestation in the urinary apparatus. It is usually transitory, and may be accompanied by hematuria. The genital organs are the seat of uncommon localizations involving the testicle, seminal vesicles, and vas deferens.

Generally speaking, the nervous system is the one most fertile in symptomatic manifestations during cerebrospinal meningitis, but the abnormal forms of the morbid process are perhaps not generally well known. In them the nervous symptoms are abnormal either from the predominance of a single symptom with complete absence of all others, or from the sequelæ that remain after the patient has recovered. This frequency of sequelæ in the nervous system is so considerable that it should be thoroughly understood. Among these, facial paralysis is to be mentioned, particularly as it appears to be the most frequent. Deafness, paralysis of the cranial nerves, and hemiplegia, although less common than facial paralysis, represent the least exceptional clinical types. Some are merely temporary, and completely disappear after recovery has taken place, while others only partially disappear, leaving variable remains of their presence in their wake.

In children, hydrocephalus is one of the most important and constant of the sequelæ, while those of a psychic nature are variable, consisting particularly in disturbances of the memory, a decrease of the intelligence or of the faculty of attention, irritability, and psychic instability.

Cutaneous complications are not uncommon in cerebrospinal meningitis. The herpetic, petechial, and erythematous forms are often observed, and in these lesions the meningococcus has been found. The infection is probably secondary in the majority of cases, but it may also be primary.

The French have given particular attention to the joint manifestations of the meningococcus. The resulting arthritides almost always suppurate, and the knee is the joint most usually involved.

In the so-called larval types of cerebrospinal meningitis the patient complains of general lameness, pain in the head, neck, and loins, but nevertheless continues his work. Sometimes there is merely a simple malaise that may readily be mistaken for influenza. Some transitory, fleeting meningeal syndromes, varying from one day to another, may be met with, and should the physician see the patient when the meningeal syndrome is manifest the diagnosis is easy, otherwise not. In the latter case the question of diagnosis is delicate, and even lumbar puncture is not always sufficient to make it, and it will be only by a bacteriological examination, often only by hemoculture, that the meningococcus can be discovered.

In the fulminating forms of cerebrospinal meningitis it is evident that infection and intoxication of the entire organism are in play. The symptoms are intense fever, chills, and cyanosis of the limbs, followed by coma and death, the latter occurring occasionally before a diagnosis has been made by lumbar puncture and bacteriological examination of the cerebrospinal fluids.

ETIOLOGY OF BLACKWATER FEVER.

OWING to the fact that a great deal of the campaigning of the war was undertaken in tropical and subtropical climates, where diseases more or less peculiar to these climates were rife, a considerable amount of knowledge has been gathered with regard to the etiology, prevalence, treatment, and so on of such diseases by military medical officers. Indeed, a new page has been opened in the chapter of tropical diseases.

For some time it was believed that blackwater fever was a disease by itself, or caused by malaria or by quinine, but it now seems to be thought by many to be due to malarial infection only. Experi-

ence during the war appears to have confirmed this view in some instances.

In the *Tropical Diseases Bulletin*, November, 1918, Warrington Yorke reviews some recent literature by Joseph A. Arkwright and Elizabeth H. Lepper regarding cases of blackwater fever occurring in the Eastern Mediterranean. The conclusions of these authors are as follows: (1) Blackwater fever is due to malaria; (2) it is predisposed to by a long-standing malaria infection with repeated relapses; (3) an attack of blackwater fever is precipitated by a relapse or recurrence of malaria; (4) the ascertained maximum and minimum intervals in different cases in the service of the authors, between the arrival in a malarial country and the first attack of blackwater fever were, maximum ten years, minimum seven months; between the first recognized attack of malaria and the first attack of blackwater fever, maximum ten years, minimum fifty days; between the arrival in a country which was non-malarial and free from Anopheles, and the first attack of blackwater fever, maximum five months, miminum one month; (5) quinine, in the class of cases which the authors met, had no share in producing blackwater fever, nor had quinine treatment during or after the attack any effect in prolonging or reproducing hemoglobinuria; (6) the jaundice of blackwater fever is certainly in some cases due to bile pigment in the circulation; (7) it is possible to estimate the total amount of blood pigment in the urine, whether in solution or in the deposit, after converting it into acid hematin, modified Sahli's method. The amount of hemoglobin lost by the kidneys is much greater than would be ascertained by an attempt at direct hemoglobin estimation of the urine. The investigators, however, are convinced that the kidneys excrete only part, possibly a small part, of the hemoglobin which is lost in an attack of blackwater fever. (8) The treatment which appeared to be of most value was intravenous or rectal administration of physiological salt solution. Whether quinine is of value or not was difficult to decide, since all the author's patients had some quinine and the intensity of the attack was no doubt different in each case.

It may be recalled that Manson, in his work on tropical diseases, after a consideration of the malarial and quinine theories of blackwater fever, gave it as his opinion that it was a specific disease of parasitic origin. Garin, Girard, and Sarrouy hold the view that it is much more probable that this affection is a syndrome which can result from very diverse causes, and that in any case it is certain that the syndrome was observed fairly frequently in the course of secondary malaria of Macedonian origin. From observations and investigations made by these French authors the conclusion is reached that there is an evident relationship between the appearance of hemoglobinuria and the administration of quinine, orally or subcutaneously. Other observations and experiments appear to go to show that quinine is a factor in the production of hemoglobinuria. The question of the etiology of blackwater fever, then, is still in doubt, and, on the whole, the attitude assumed by Drs. Garin, Girard, and Sarrouy that it is a syndrome which may result from several causes, seems to be supported by the weight of authority.

POSTOPERATIVE GASTROINTESTINAL HEMORRHAGE.

Gastric or intestinal hemorrhage may be encountered after any surgical interference, no matter of what nature, but unquestionably it is more prone to occur after an abdominal operation, particularly when the interference has been for the relief of some lesion of the digestive tract. This means that it must be due on the one hand to local factors, such as primary lesions of the digestive tract or peritoneum, or on the other hand to general causes, such as infection, intoxication, or perchance to reflex disturbances.

Infection, be it localized or general, is the most common etiological factor, although it may occasionally be difficult to attribute the respective parts played by septicemia and chloroform poisoning when the latter drug has been used as the anesthetic. In point of fact, chloroform may not only set up hemorrhages in a predisposed soil, but it is likewise quite capable of determining by itself a sanguineous dyscrasia with a gastrointestinal localization.

The other major etiological factors are traumatic or mechanical lesions of the digestive tract, which may or may not be attributable to a defective technique, such, for example, as prolonged operative maneuvers on the omentum and extensive resections of this viscus. The nature and seat of the lesions of the digestive tract are very variable, according to the pathogenesis of the hemorrhage. The most frequent, however, is a hemorrhagic erosion or deep ulceration almost always seated in the gastric or duodenal mucosa. In 25 per cent. of autopsies no gastrointestinal lesion could be discovered.

The clinical picture of these hemorrhages also varies greatly, and the most sagacious medical mind will be quite unable to make a diagnosis of the exact mechanism of the hemorrhagic complication unless all details of the operative interference and symptoms offered by the patient are passed in review, not overlooking the time of the appearance of the loss of blood.

The prognosis of postoperative gastrointestinal hemorrhage is subordinated to both the amount of blood lost and the gravity of the concomitant symptomatic *ensemble*. Generally speaking, a very reserved prognosis should be made, because out of a total of 249 cases reported by Fourdinier death occurred in 130; in other words, a mortality of 52 per cent. Purves found a mortality of 72.5 per cent. while Busse came to a mean death rate of 55 per cent. These hemorrhages especially demand a reserved prognosis when they arise after operations not involving the digestive tract, and out of a total of fifteen cases of extra-abdominal operations where

this complication occurred fourteen died. In purely abdominal operations the prognosis is less gloomy, as out of a total of 74 cases there were 44 deaths, or a mortality of 59 per cent. In operative work on the digestive tract, the prognosis, although in itself serious, may be considered as relatively benign, because out of a total of 160 gastrointestinal operations there were 72 deaths, or 45 per cent. Simple hernia operations followed by gastrointestinal hemorrhage have given a mean death rate of 40 per cent., while in the case of strangulated hernia it is found to be 37 per cent., and 50 per cent. in appendicitis. Therefore, according to Sauvé, one should separately consider early hemorrhage, arising during the first four days following the operation, and late hemorrhage occurring after the fifth day. In Busse's statistics there were only 30 deaths out of a total of 56 cases of early hemorrhage, while for late hemorrhage the mortality reached nearly 80 per cent. These proportions remain about the same in all the statistics from various countries.

Surgical treatment is occasionally indicated, but usually the care of the case remains strictly medical. In certain circumstances, prophylactic measures should be carried out in order to forestall the possible occurrence of a post-operative gastrointestinal loss of blood.

Nephritis from Suppuration of the Skin.

The amyloidosis of the kidney which follows protracted and extensive suppuration is probably not akin in any way to nephritis which is believed in the Orient to follow chronic impetiginous affections. Such a sequence at once recalls albuminuria following scabies, although such sequence is rare with us, and actual nephritis is extremely rare. A recent medical graduate, Farah, a resident of the Orient, has devoted a Paris graduation thesis to this subject, reviewed in the *Journal de médecine et de chirurgie pratiques* for September 10. That young children with impetigo may develop nephritis has also been shown by Hutinel, the well-known pediatrist. Since scabies is clinically the most pronounced type of impetigo, it need not surprise us to learn that it is the most common factor in the Orient in the genesis of this renal lesion. This nephritis may be of several types, from the banal nephritis with massive albuminuria, edema, and oliguria, to simple hematuria or albuminuria. In certain cases there are marked intrathoracic complications, while enlargement of the liver and spleen appears to be the rule in the young child. While recovery is the rule, fatalities from uremia have occurred. In treating these cases the main indication is to remove the cause of suppuration, after which the kidneys are treated in the usual manner, chiefly with diet.

Cure of Malignant Disease of the Testicle.

Statisticians have claimed that the prognosis after removal of testicles which have undergone malignant degeneration is unusually hopeless. This is true especially of carcinoma. But if exceptions ever can be said to prove rules, then Professor Loumeau of Bordeaux has recently furnished two proofs, reported in the *Journal de médecine de Bordeaux* for October. In 1900 he castrated a man 35 years of age for a tumor which proved to be a spindle-cell sarcoma. This subject is still living, as is another who in 1910 was castrated for cancer (epithelioma) of the testicle. The second man was 47 at the time of operation. The most remarkable feature about these cases was the fact that Loumeau, perhaps anticipating that radical intervention would be useless, performed what would be termed ordinarily a palliative operation. He simply excised the testicle, and made no attempt to remove the inguinal glands, although this step is almost obligatory in cancer, which diffuses through the lymphatics. It is, of course, more optional in the case of sarcoma, in which propagation by lymphatics is very rare, if in this location it occurs at all. Had the usual sequence occurred, the lymphnodes of the prevertebral region would, in the cancer patient, have become infected, and the knife could not have been invoked to stay the process.

News of the Week.

Surgeon General Blue Proposes Health Sunday.—Surgeon General Blue of the Public Health Service has asked the ministers of the country to set aside Feb. 23 as Public Health Sunday, and to preach sermons emphasizing the responsibility of the nation to protect the health of the returning soldiers and sailors and of the community at large, and particularly to take vigorous measures for combating social diseases. A formal proclamation has been sent to all ministers pointing out that drastic measures must be taken to prevent, during this period, those conditions in civilian life which made these diseases the greatest cause of disability in the army. The cities and towns through which the soldiers go in the process of demobilization must be made as safe as the camps. In closing, the proclamation urges the importance of this responsibility "in order that the world may be made not only safe for democracy, but safe for posterity."

Harvey Society Lecture.—The third Harvey Society lecture of the season will be given by Dr. R. M. Yerkes at the New York Academy of Medicine, on January 25, at 8.30 P. M. The subject will be "Psychological Examination of the Soldier."

Legislators Wear Masks.—The State Senate in session at Sacramento, Cal., has waived its constitutional immunity from the provisions of the city's influenza mask ordinance and has prohibited the entrance into the Senate chamber of any person unmasked.

Pennsylvania Death Rate for 1918.—The death rate for the year 1918 was the highest in the history of the State Health Department in Pennsylvania according to the report of the State Registrar. Approximately 185,000 deaths occurred, the rate being 21.6, as compared with 14.8 for 1917. This increase is due almost entirely to influenza, which caused more than 50,000 deaths.

Commission to Fight Hookworm.—The Rockefeller Institute is planning to send a commission to Jamaica to take charge of a campaign against hookworm disease. A recent census shows that

20 per cent. of the population of Jamaica is infected.

New Departments in Georgia State Board of Health.—Two new departments, one of vital statistics and one of epidemiology, were placed in operation in the Georgia State Board of Health on January 1. These divisions will provide a clearing house for all the other activities of the departments and are expected to prove valuable addition. Dr. W. A. Davis of Austin, Texas, has been placed in charge of the department of vital statistics, and Dr. F. M. Haygood of LaGrange will take charge of the epidemiological department.

The New York State Department of Narcotic Drug Control, created by Chap. 639 of the Laws of 1918, supersedes on February 1, 1919, the "Bureau of Habit Forming Drugs" under the State Board of Health. Under the new law, every physician, druggist, dentist, veterinarian, hospital, sanatorium or other institution, wholesaler or manufacturer, prescribing, administering, dispensing, selling or manufacturing cocaine, opium or its derivations must during the month of January, 1919, file an application and receive from the department a certificate of authority to deal in habit forming drugs. This registration is for the balance of the State fiscal year and requires no fee. Thereafter, during the month of June in each year, he shall in like manner register with the Department and for this and each subsequent registration shall pay the department a fee of $1.00.

Urges Abolition of Drug Control Board.—Governor Smith has asked the New York State Legislature to immediately abolish the State Narcotic Drug Control Commission as an unnecessary bureau entailing needless expense to the State. In a special message to the lawmakers he suggests that the work of the Commission be taken over by a bureau to be created in the State Department of Health. Governor Smith in his message states that he is in sympathy with the purposes of the law and believes that the State should provide for the regulation and control of the sale of narcotic drugs. He believes, however, that inspectors and other employees of the State Health Department who are performing similar duties could at the same time give their attention to the enforcement of the law regulating the sale of narcotic drugs.

The Annual Report of the Surgeon General of the Public Health Service for 1918, has been issued recently, and gives a long, instructive, and interesting account of the work done by this service during the fiscal year 1918. Owing to the war, many health problems have had to be grappled with which are absent in times of peace. For example, the laboratory and field investigations have related almost entirely to health problems arising from the war. Perhaps the most important of the various activities of the service during the period covered by the report have been exercised in connection with venereal disease, and it may be said that the efforts in this direction, intelligently conceived and carried out, have been attended with marked success. The report, in every page, demonstrates the fact that in the Public Health Service the country possesses vigilant guardians of the health of the nation.

Rigid Prohibition Measure for New York.—Legislation to enforce prohibition in New York State, in ratification of the Federal amendment, has been drafted for introduction to the Legislature. Among the regulations controlling the sale of alcohol are very strict provisions affecting druggists and doctors. The law would allow a druggist to make no sale of alcohol for medicinal purposes except upon a physician's prescription and an affidavit would be required of all persons purchasing for mechanical, chemical or sacramental purposes. A pharmacist's license to sell alcohol or wine would be issued only to druggists who have never been convicted of an illegal sale of liquor, whose stock of alcohol on hand shall not represent more than one per cent. of the value of all the goods in his place of business, who are of temperate habits and not addicted to the use of alcohol or drugs, and who will not sell to any person known to be in the habit of using alcoholic beverages. The sale of toilet, culinary, medicinal, antiseptic and flavoring extracts and patent medicines, the manufacture of which requires payment of a United States liquor dealers' tax, would be prohibited. No one but a licensed druggist would be permitted to sell certain proprietary compounds and patent medicines named in the bill except upon the prescription of a licensed physician. Physicians would be required to keep a record of all prescriptions issued by them for alcoholic compounds, and the medical practitioners allowed to issue such prescription would first have to give bond of $2,000 for observing the provisions of the law and be licensed by the prohibition commissioner.

Labor Unions Protest against Changes in Health Department.—The Secretary of the Central Federated Union of New York, Ernest Bohm, has sent a circular letter to the affiliated unions having a membership of 300,000, calling their attention to the action of Health Commissioner Dr. Royal S. Copeland in removing the Division of Industrial Hygiene from the Bureau of Preventable Diseases, of which Dr. Louis I. Harris is Director, and urging them to protest to Mayor Hylan and Commissioner Copeland against what is termed a "conspiracy" against organized labor. The Woman's Municipal League, in its forthcoming Bulletin, will also protest "against the narrowing of the scope of the Bureau of Preventable Diseases," and will call on its members and the members of all civic bodies to join in the effort to have Dr. Harris's power restored. A mass meeting of organized labor to arouse workers to a defense of their rights to health protection was called at Washington Irving High School on January 22.

Mr. Horace Fletcher, the proclaimer of the theory that the more one chewed his food the less food was it necessary for him to eat, died of bronchitis after a long illness, in Copenhagen, on January 13, at the age of 70 years. During the war Dr. Fletcher had been a food economist for the Commission for the Relief of Belgium and had been teaching his system to millions of starving Belgians. Dr. Fletcher was a member of the Committee of 100 on National Health, President of the

National Mouth Hygiene Association, a member of the National Commission on Mental Hygiene, vice-president of the Food Reform Society of England, and many other health, sociological, and geographical societies and was the author of several books on his mastication theories.

Dr. Roy K. Flannagan has tendered his resignation as chief health officer of the city of Richmond, Va.

Dr. George A. Carpenter of Fargo, N. D., has been appointed superintendent of the Cass County Board of Health.

American Women Establish Hospital in France.—American women suffragists, in honor of the Maid of Orleans, have established at Nancy, the Hôpital de Jeanne d'Arc. The hospital is designed especially for the treatment of women and children patients who have lacked adequate hospital facilities since military requirements necessitated the taking over of nearly all the French hospitals.

Charitable Bequests.—The Presbyterian Hospital, New York, is the recipient of a bequest of $5,000 under the will of Elizabeth H. Keyes.

Medical Society Elections.—The Cass County Medical Society, at its annual meeting held in Fargo, N. D., Jan. 6, 1919, elected the following officers for the ensuing year: *President*, Dr. J. P. Aylen; *Vice-President*, Dr. J. W. Awty; *Secretary*, Dr. Paul Burton; *Treasurer*, Dr. Paul Sorkness.

The Madison County (Ala.) Medical Society, at its annual meeting held in Huntsville, January 6, 1919, elected the following officers for the ensuing year: *President*, O. J. Brooks; *Vice-President*, Dr. E. O. Williamson; *Secretary-Treasurer*, Dr. M. M. Duncan; *Jail Physician*, Dr. Carle Grote; *Poorhouse* Physician, Dr. C. E. Blanton.

The Guilford County (N. C.) Medical Society, at its annual meeting, January 2, 1919, elected the following officers for the ensuing year: *President*, Dr. J. T. J. Battle; *Vice-President*, Dr. A. R. Wilson; *Secretary-Treasurer*, Dr. R. A. Schoonover.

Obituary Notes.—Dr. Charles D. Kelly, a graduate of the Medical Department of the University of Vermont, in 1894, died suddenly of heart disease at his home in Mount Vernon, N. Y., on January 17, aged 59 years.

Dr. Thomas Kelly of New York City, a graduate of the New York University Medical College, in 1884, died suddenly in his carriage, while making his calls, on January 17, aged 55 years. He was on the staff of consulting physicians of St. Vincent's Hospital, visiting physician at the St. Lawrence Hospital, the Catholic Institute for the Blind, and the Seton Hospital at Spuyten Duyvil.

Dr. S. Wooley, retired, of Madison, S. D., died following a month's illness of acute uremia, on December 29, aged 75 years. He formerly served for a time as health officer of Madison.

Dr. J. D. Massengill, a retired physician of Blountville, Va., died after a long illness, on January 10, aged 75 years. He was a Confederate veteran, having served during the entire war.

Dr. Frederick H. Humphreys, a graduate of the University of Vienna, in 1872, President of the Humphrey's Patent Medicine Company, died at his home in Morristown, N. J., on January 14, aged 72 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

AN INTERESTING CASE OF IMPERSONATION—THE VISITS OF MEDICAL MEN TO LUNACY PATIENTS—DEATH OF TWO WELL-KNOWN NEUROLOGISTS—MEDICAL CANDIDATES FOR PARLIAMENT.

London, January 2, 1919.

A case has been recently heard in a police court which has certainly a very disquieting appearance for those who believe that the Medical Acts and the Official Register of the medical profession, kept in accordance with those Acts, preclude the possibility of a layman impersonating a medical man. The story in question is as follows: Some twenty years ago a Mr. James Allan, a medical graduate of the University of Edinburgh, died, but in 1901 the name and qualifications of James Allan, M.B., C. M. Edin., appeared in the Medical Directory. The Medical Directory is the private property of the well-known medical publishers, Messrs. J. & A. Churchill, and is edited with conspicuous care. It is not, however, an official publication, and has not the same facilities as those possessed by the General Medical Council for maintaining an accurate list of the profession. The official list of the profession is known as the Medical Register. The new James Allan was at one time an unqualified medical assistant, having been at some period or another a medical student, but on the strength of his name appearing in the Medical Directory he set up in practice as a medical man in the neighborhood of London and conducted his business with propriety, and apparently with efficiency. But he got his name into the Medical Directory by misrepresentation. In a sense, it may be said that it was his good work which revealed his fraud, for when the war broke out James Allan proceeded to do excellent auxiliary medical work in his neighborhood, work of such a quality that he received titular distinction, being made an officer of the Order of the British Empire (O. B. E.). His appearance in the Gazette as an O. B. E. led his name to be searched for by the Registrar in the Medical Register, where it was absent, although it appeared with the title added in the Medical Directory. Further investigation showed that the deception had been practised for nearly twenty years. James Allan was fined £20 and £10 costs for having used medical titles unlawfully, a more serious charge that he had illegally signed certificates of death not being proceeded with. The sentence is, of course, extraordinarily light, the magistrates no doubt taking into consideration—kindly, if illogically—two things: first, that in the conduct of his practice, as far as could be ascertained, he had made no clinical or professional lapses; and secondly, that any conviction, whether punished by light or heavy pecuniary fine, must mean the immediate destruction of his financial position. But no medical man can possibly regard the position of James Allan in this amiable light. Apart, however, from this, the facts show that impersonation is by no means so difficult as the Medical Acts are designed to render it. It is suggested that the later James Allan may have actually bought the diploma-documents of the previous deceased James Allan from the widow, in which case he would have written evidence to pro-

duce when applying to have his name inserted in the Medical Directory; and anyhow, this would be a very likely way of obtaining that insertion. His name being once in the Medical Directory, his position seems never to have been challenged by anybody, though consultation of the Medical Register at any time during a long range of years would have suggested the plot. No one can legally sign a death certificate whose name does not appear in the Medical Register, but neither the public nor the medical profession will take the trouble to consult the official roll. No one but a man whose name is in the Register can give medical evidence, as a doctor, in a court of law, and in consequence a medical witness is usually asked if he is "on the Register." The question, however, has been omitted before now by barristers who do not know their work, it being simply put to the witness that he is a "doctor." Of course, any one can assume the title of doctor; such assumption only becomes illegal when pretence is actually made to the legal position.

The situation dependent on the refusal to give Dr. Lionel Weatherly, the well-known alienist, proper facilities for examining a patient resident in a public lunatic asylum has already been referred to in these letters. (See MEDICAL RECORD, Dec. 14, p. 1039.) Briefly, the story is that Dr. Weatherly was asked to visit the patient by the patient's friends, where the superintendent of the asylum at first refused the necessary permission, but later withdrew the refusal at the instance of the Board of Control (Lunacy). This board is responsible for the regulations which govern public or county lunatic asylums, and it recognised that Dr. Weatherly was only asking for a right given to him by Act of Parliament. But the leave to visit the lunatic so obtained was rendered of no scientific value by the fact that Dr. Weatherly was refused permission by the superintendent to see the notes of the patient's case or to interview the medical man in direct charge of him. Dr. Weatherly accordingly applied to the Board of Control for further facilities, but could not obtain them, and the story, when last reported, was left at that stage, the probability that the help of the law courts would be sought being obvious. At the beginning of December a divisional court of the King's Bench, upon application by the brother of the certified lunatic, granted a rule against the commissioners of lunacy; in other words, the commissioners of lunacy, who are the executive officers of the Board of Control, were enjoined to appear before a High Court of Justice and give their reasons why they did not grant Dr. Weatherly the facilities which he sought. A strong bench of three High Court Judges listened to the arguments, and decided in favor of the commissioners, a ruling which cannot possibly be satisfactory to the public. This decision, however, was anticipated by most people who have had any experience of the thankless task of arraigning a public department before a Court of Justice. A clause in the Lunacy Act reads as follows: "If the manager or principal officer of any institution or place refuses or prevents or obstructs the admission to any patient of any person who produces an order of admission, he shall for every offense be liable to a penalty not to exceed £20." Now, Dr. Weatherly was certainly "admitted to the patient," but the practical utility of the visit was nullified by his being able to obtain no interview with those in clinical charge of the case, and no written records of the case. To medical men, as well as to the public, it will seem that the Commissioners of Lunacy obtained their verdict in consonance with a literal interpretation of the law which defied the spirit of the law. It is quite possible that more may yet be heard of an important altercation.

During the last few days death has suddenly removed from the ranks of the medical profession two well-known neurologists, both senior physicians to the Hospital for Epilepsy and Paralysis, in Maida Vale, Dr. George Ogilvie and Dr. Leonard Guthrie. They were well-known men in totally different capacities despite their closely interwoven medical interests. Ogilvie, a large, fair man, was notoriously one of the best after-dinner speakers in London, wore on his breast the orders of knighthood of three foreign countries, and expounded in practice the more general tenets of neurology, especially in relation to questions of heredity. Guthrie, a dark and tiny man, was absolutely self-effacing. Only his personal friends knew either his wide learning or his whimsical powers of humor. He was a neurologist of the most advanced scientific school, a wise author on pediatrics, the chairman of a committee of the Royal College of Physicians of London on Medical Nomenclature, an examiner in medicine at Oxford because he represented modern science, and Fitz Patrick lecturer at his college because he was a storehouse of ancient medical history. Ogilvie died after a very brief illness following a fall, and within a few days Guthrie, who had succeeded him at Maida Vale as senior physician, was struck by a passing train while standing on a platform, dying a few hours later.

The recent general election showed a distinct increase in the number of medical men who desired to obtain seats in Parliament, no less than 36 having been candidates. Of these, twelve new members were successsful, namely: Dr. McCartan, Dr. B. Cusack, Mr. John Crowley, Dr. W. E. Eliot, Dr. A. C. Farquharson, Dr. B. F. P. McDonald, Dr. J. E. Molson, Dr. Donald Murray, Dr. Nathan Raw, Dr. James Ryan, Sir William Whitla, Sir Robert Woods, along with three others who have already established their position in the House of Commons, viz., Dr. Christopher Addison, Sir Watson Cheyne, and Sir Auckland Geddes.

The medical candidates stood on all sorts of political tickets or programs, which is as it should be, for the right of a medical man to sit in Parliament is due only to his desire to promote the cause of health and sanitation; the shade of his political feelings on other questions is so entirely unimportant compared to his resolute convictions on the main subject that whatever the electors may do his medical colleagues can afford to forget whether a doctor in Parliament is a *quâ* politics, a Tory or a Liberal, or a party creature, or even an avowed rebel. The Parliamentary Medical Committee, whose constitution and activities have been noted in several previous letters, does not speak as openly as this but their public views are on the same lines. The medical profession in Great Britain has agreed that it requires a louder and clearer parliamentary voice, and with some qualms it has also agreed that to obtain that voice the usual customs at elections must

be followed. A man must stand if he is to have any chance of success in accordance with a political program. No man will get into Parliament on his medical claims only. But the ideal medical man in Parliament should not represent medicines only; he should be the interpreter of medical thought and aims to his fellow legislators. This he can easily be while assenting to a general party creed, provided that in every word that he utters and in every idea that he supports the predominant claims of national health are obvious. Such a legislator can conform to party politics and can keep his necessary pledges to his constituency and to his political organization, while remaining faithful to ideals outside and above such pledges.

It should be added that the Medical Parliamentary Committee, although it was born only when the general election was actually upon the country, managed to show itself of considerable use. For the committee supplied speakers to several platforms whose interpretation to the public of medical ideals was certainly valuable.

LETTER FROM CANADA.

(From an Occasional Correspondent.)

THE HOUSING QUESTION IN CANADA—VACCINATION REGULATIONS IN THE PROVINCE OF QUEBEC—PROHIBITION IN CANADA—DEMOBILIZATION AND THE VENEREAL PROBLEM—DOMINION ORTHOPEDIC MILITARY HOSPITAL IN TORONTO—MAJOR F. N. G. STARR IN FRANCE—THE JORDAN MEMORIAL HOSPITAL, NEW BRUNSWICK—DEATH OF DR. A. ORR HASTINGS.

MONTREAL, January 11, 1919.

It appears that one of the results of the war in Great Britain and in the Dominion will be greatly to improve the conditions under which the working classes live. Public health will be a prominent plank of political platforms. It is fully recognized that a first essential step in this direction is to improve the housing conditions of working people, and especially those of large cities and of industrial centers. Slums constitute a menace to the health of the entire community, and merely as a matter of self defence all the population should be housed decently. While the death rate generally, and infant mortality in particular, have been very considerably reduced in recent years, on account of improved methods of living and sanitation, there are in all large cities certain areas in which the death rates are enormously and disproportionately higher than others. As said before, these "black spots" of a city not only adversely affect the death rate of the whole city but are a standing public menace because they are generally the sources of disease, and supply the means by which infectious diseases are spread. It goes without saying that density of population and the overcrowding exemplified by several persons living in a room lead to high death rates. As a rule, the rates of mortality vary almost in exact proportion to the number of one and two-roomed houses in a district, or as Dr. Farr, in his recent work on vital statistics puts it, "The greater the proximity of man to men the greater is the mortality."

The Canadian Government a short time ago evinced in a practical manner its appreciation of the housing situation and its bearing on public health by voting twenty-five million dollars to improve housing conditions. The Toronto Bureau of Municipal Research has condemned conditions in a part of that city known as "The Ward," and in addition has made certain recommendations with a view to bettering the lot of the dwellers. One suggestion is to the effect that housing by-laws should be carefully drafted to meet the needs of the situation. However, every big city has a similar problem. Probably there are few cities of the New World, or, for that matter, of the Old World, in which the quarters where the poor exist are worse than in Montreal. The limelight was thrown on this phase of the public health question during the recent epidemic of influenza. It was then brought to the attention of all citizens that unsanitation, overcrowding, and indecent squalor were the prevailing characteristics of the slum districts of Montreal. It must be borne in mind that the municipality owes a duty to every inhabitant of a city. Good houses, with a sufficiency of air space, should be erected in all centers of population, and further adequate housing laws must be framed and enforced. Also the local authorities must insist that streets and lanes be kept clean. All this can be accomplished if money, energy, and initiative are forthcoming, and every one concerned directly and indirectly, will be infinitely better for the introduction and carrying out of these greatly needed reforms.

Prevention is better than cure, and it is impossible to raise a healthy race unless measures calculated to prevent disease, of which good housing and environment are essential factors, are well within the reach of the working classes, who, after all, constitute the majority of a population.

The superior health officers of the Province of Quebec, as a precautionary measure, have ordered all the municipalities of the province to pass by-laws enforcing vaccination. There have been a few cases of smallpox in seven municipalities, other cases have been reported from neighboring provinces, and the inspectors of the board have not been able to trace the source of all the cases. In order to prevent as far as possible the spread of the disease it has been deemed advisable to bring all municipalities into line with regard to the vaccination laws. About seven hundred of the twelve hundred municipalities in the province already have a compulsory vaccination law, and the order requiring the passage of such a law has been sent to the remaining five hundred municipalities.

The matter of prohibition is greatly exercising the minds of the general public and of those interested in the liquor trade at the present time. Prohibition was passed in all Canada as a war measure, with the exception of the Province of Quebec, while it was enacted that prohibition should become law in Quebec in May next. A good deal of dissatisfaction exists with respect to prohibition, especially among the working classes, and it is now argued by a part of the population that with the cessation of hostilities the prohibition laws should be repealed, or at any rate modified, and that so far as Quebec is concerned they should not be enforced. On the other hand, the advocates of prohibition, and these perhaps preponderate in number, contend that the laws abolishing alcoholic drinks have answered so well that they should continue in force. Sir William

Hearst, premier of Ontario, bluntly told a deputation of the provincial executive of the Dominion Trades and Labor Congress that the Government of Ontario does not intend to depart from its present temperance policy. The existing provincial legislation will remain virtually unchanged until a year after the war, when a referendum will be taken. The deputation asked that beer of 2½ per cent. alcoholic strength should be permitted instead of 2½ per cent. proof spirit as now. Sir William pointed out that the province could not alter the Dominion's provision in this respect. He noted that some labor men had not hesitated to express themselves in favor of prohibition laws. He believed their enforcement had made for efficiency and for the good of the community from the social standpoint, and indeed from all points of view, in the Province of Ontario. In support, doubtless, of the stand that alcohol is unnecessary and harmful, and perhaps in rebuke to those who took advantage of the epidemic of influenza to use alcohol for medicinal or ostensibly for medicinal purposes, the Premier quoted from the report of the American Public Health Association to the effect that alcohol was not beneficial to influenza patients.

There is no feature of demobilization which looms so large as that of venereal disease. General Mewburn, Canadian Minister of Militia, spoke recently on demobilization, of the Canadian forces and the difficulties connected therewith. Referring to the venereal question, he said: "One of the greatest dangers the nation has to cope with is the venereal trouble." He went on to mention that his adjutant general and the army medical officers said: "No, we have a duty to the nation, and we must hold these men and make them fit before being discharged, so that they will not be a menace when they go back into civil life." There is no doubt that this attitude is wise and justified by the circumstances. In any event, however, the increase of population by the influx of thousands of soldiers with money, many of whom will live in idleness for some time, will greatly complicate the venereal situation and vastly increase the problem of the streets of cities. In Canada, perhaps Montreal is the city in which the social evil is most evident. Prohibition is not in force, and according to the report of the committee of sixteen it contains a large number of houses of prostitution. Moreover, the demobilized soldiers land in Montreal, and are apt to stay in a city in which allurements are many, and unfortunately also are liable to contract venereal disease. An important conference on social hygiene was held in Toronto on November 14 and 15 last, under the auspices of the advisory committee on venereal diseases, No. 2 Military District. The meeting, presided over by Colonel McCullough, chief officer of the Ontario Board of Health, was held for the purpose of launching a nation-wide campaign against vice. One of the principal speakers was Madame Avril de Ste. Croix, president of the International Commission of Women for Unity of Morals, and there were present delegates from Montreal, Ottawa, Hamilton, and Toronto. Among the resolutions drawn up by the resolution committee were the following: That this conference is of the opinion that the use of alcohol contributes largely to immorality and its consequent venereal disease, and therefore puts itself on record in favor of nation-wide prohibition. That the problem of housing, especially in regard to young women living alone, is very acute, and should be dealt with energetically by the government and communities, in that bad housing conditions are regarded by the conference as a strongly contributing factor in the production of immorality and venereal disease. That the conference appreciates the action of the Ontario government in enacting valuable legislation, and feels that measures should be taken to see that there be coordination between the various provinces in the passing and enforcing of such legislation. Capt. Gordon Bates, C. A. M. C., of Toronto, in an able paper read before the Canadian Medical Congress, May, 1918, and published in the *International Journal of Surgery*, September, 1918, points out that investigations among troops quartered in Toronto revealed that the cases which were treated at the Base Hospital for No. 2 Military District had not all received their infections in Toronto, and that while over 50 per cent. of the infections had taken place in Toronto, infected men came in not only from almost every town and city in Ontario, but from other provinces, the United States, and from many other parts of the world. It was found that in a few parts of Canada organized prostitution existed on a fairly large scale. But it was also found that what may be termed promiscuous intercourse was frequent in Ontario cities, and was a fruitful means of spreading infection. It was discovered that in certain dance halls it was easy for men to pick up young girls, and that many girls who frequented these dance halls were both immoral and infected. When such a situation exists it may be gathered that the task of stamping out venereal diseases is rendered vastly more difficult. A diseased woman can spread the infection far and wide, and in order to prevent this means of dissemination the woman must be known and the necessary steps taken. The case of professional prostitution presents no great difficulties, but it is altogether a different matter in the case of the non-professional. However, it is most encouraging to notice that in the Canadian cities intelligently conceived and far-reaching methods are being put into force to safeguard the returned soldiers and also to prevent the soldiers from conveying infection. In fact, determined efforts are being made to decrease the volume of venereal infection, and, if possible, to stamp it out. A particularly encouraging feature in connection with the campaign against venereal disease in eastern Canada is the enthusiasm with which the question has been taken up by prominent women.

The Dominion Orthopedic Military Hospital of Toronto, formerly the National Cash Register factory, will be opened on February 1. It has a capacity of 600 beds for amputation cases and cases of internal injuries.

Major F. N. G. Starr, the well-known Toronto surgeon, is stationed at No. 14 Stationary Hospital, France.

The Jordan Memorial Hospital, New Brunswick, was presented to the province by Mrs. J. Clarke Jordan, who has expressed her willingness that it should be used as an institution for soldiers. It has passed into the hands of the Invalided Soldiers' Aid Commission.

Dr. A. Orr Hastings, a well-known physician of Toronto, and brother of Dr. Charles J. C. O. Hastings, head of the city health board, died on November 21.

3. Envenomization Suggested as Etiology of Obscure War Diseases.—Anne Young briefly reviews the part played in the production of toxic and pathologic conditions in man and the higher animals by various insects and venomous animals, and suggests that symptoms of war diseases and other diseases of obscure origin may be explained by the pathologic changes following the introduction of an animal secretion, excretion, or tissue. This author points out that, aside from those referable to the special organ or part involved, the symptoms of all war diseases read wonderfully alike. Symptoms are controlled by the size of the dose of venom, and their character depends upon whether the venom is pre-eminently a neurotoxin (*e.g.* cobra venom) or a hemotoxin, such as the venom of the rattlesnake or Russell's viper. (The author remarks that the fact that the hemolytic power of venoms is not operative on all blood cells alike may account for the reported increase of the red cells to hemolysis while jaundice lasts in cases of epidemic jaundice. It has also been noted that while treating cobra venom with blood in the experiment of making cobra lecithin the acidity is raised. At a certain point the process is checked and it is not until an alkali is added that the process proceeds to the formation of the thermostable lecithin. This observation may explain the temperature remissions of many fevers of known bacterial origin and those of obscure etiology, such as trench fever.) The life cycle of insects may explain the peculiar outbreaks and disappearances of epidemics, even when of bacterial origin, as there are probably many symbiotic relationships between insects and bacteria. In the author's opinion the outstanding inference from this survey of literature is that the digestive secretions, excretions or tissues of animals may act as a venom when introduced into the tissues of another animal.

2. The Effect of Heat on the Spores of the Bacillus Botulinus: Its Bearing on Home Canning Methods. Part I.—Georgina Spooner Burke gives the results of a series of experiments undertaken to determine the effect of heat on the spores of the *Bacillus botulinus.* The work was prompted by seven cases of botulism investigated during the winter of 1917 to 1918 by Dr. E. C. Dickson, of the Leland Stanford, Jr., School of Medicine. (A report of these cases is in process of publication.) From the experiments made the author concludes: (1) Free spores of *B. botulinus,* grown in either broth or brain cultures, are highly resistant to heat. (2) Spores grown in brain cultures are more resistant than spores grown in broth cultures. (3) Exposure of the spores to a temperature of 100° C. or more inhibits the development of the spores of *B. botulinus* so that the incubation period is very much increased. (4) The method of canning by boiling the fruit or vegetables in an open kettle and sealing in clean jars cannot be relied on to sterilize material that is contaminated with spores of the more resistant strains of *B. botulinus,* since spores of *B. botulinus* will survive in boiling liquid for three and one-half hours; and in the foam that gathers on the side of the kettle they may live for a much longer period. (5) The sterilizing processes of the cold pack method are not sufficient to kill spores of *B. botulinus.* (By this method the fruit is blanched, then packed in jars, and the jars put into water and boiled for one continuous period of from one and a half to five hours.) Blanching in boiling water for five minutes is effective as a cleansing agent, but it does not materially injure spores of resistant strains of *B. botulinus.* One period of heating in boiling water for five hours or less will not sterilize the contents of jars if they are contaminated with the more resistant spores of *B. botulinus.* (6) Fractional sterilization on three successive days is of doubtful value because, after exposure to a temperature of 100° C. for from fifteen to sixty minutes, the germination of the spores is retarded so that they do not develop before the third sterilization period. (7) Pressure canning is the only method of sterilization that at present can be considered safe. But a pressure of 5, 10 or 15 pounds for ten minutes will not kill the more resistant spores of *B. botulinus.* Therefore a comparatively long sterilization period must be used. (8) With our present knowledge, the best way to guard against spoilage of canned goods due to *B. botulinus* is to prevent spores of this organism from entering the jars. The source of contamination is not at present known. (The author is collecting material in an effort to secure data bearing on this.) It is quite certain that the organism is not present under the skin of perfectly sound fruit and vegetables that are not overripe. Therefore, fruit and vegetables of this sort should be used. Bruised and partially spoiled material, if it is fit to use at all, should be consumed at once and not stored for future use. The fruit and vegetables should be thoroughly cleaned before they are peeled or cut in order that no foreign matter may be crushed into the pulp where it would be protected. It is possible that the spores of *B. botulinus* get into the jars from some source in the kitchen. For this reason it is essential that the hands and all utensils be made as clean as possible and that flies be eliminated. The use of sound fruit and clean methods of handling are the most important factors in canning, so far as *B. botulinus* is concerned, because the sterilization processes in common use will not kill all the spores. (9) It is important that housewives be warned of the danger of *B. botulinus* spoilage so that they may examine every jar carefully when it is opened for table use. The contents of the jar must not be tasted to "see if it is spoiled." The smallest taste will be fatal if the toxin is strong. There are three signs of spoilage from *B. botulinus,* any one of which is sufficient to condemn the jar. These are: (*a*) Gas bubbles in the jars, the tops of the jars blown and a squirt of liquid as the top is unscrewed; (*b*) an odor somewhat resembling rancid cheese; (*c*) a mushy or disintegrated appearance of the solid parts of the contents of the jars. (10) The toxin that *B. botulinus* produces after several weeks or months growth in a sealed jar may be entirely destroyed by boiling for five minutes, although the spores of *B. botulinus* are not killed by this treatment. It is the toxin and not the spores that produces illness, for the bacilli do not produce toxin when taken into the body. Therefore, any canned goods that are in the least suspicious should be emptied into a kettle and boiled for five minutes. They can then be eaten without danger. (11) Since *B. botulinus* produces toxin only in material that has

been sealed in an air-tight container for a week or more, and since it produces no toxin in the human body, there is no danger of botulism from uncooked fruit or vegetables or from those freshly cooked.

1. An Address on Lethargic Encephalitis.—E. Farquhar Buzzard, in an address delivered before the Medical Society of London on December 9, 1918, points out that, though the fact is not realized sufficiently by the profession, encephalitis, or inflammation of the brain, is by no means uncommon. He states that for years he has urged the view that disease of the brain and spinal cord, produced by the virus of poliomyelitis, should be regarded as an acute specific fever which has a special incidence upon infants and children, the susceptibility to the infection decreasing as age advances. (The author has met with only few cases after 25, and none after 40 years of age.) Other forms of encephalitis, such as an occasional complication or sequela of typhoid fever, are more rarely encountered. It should be remembered, however, that there is a form of encephalitis which has the constitutional disturbances, the age incidence, the seasonal exacerbations, the sporadic and epidemic types, and the immunity from second attacks which are shared by measles, scarlatina, and other acute specific fevers; that it presents an inflammatory lesion of a particular tissue as in typhoid, diphtheria, and smallpox, and that it has been shown to be due to the virus of poliomyelitis. It is an acute infection, running its course in a few days, but often leaving permanent results in the form of paralysis, mental defects, and epilepsy. The epidemic which recently occurred in England is an entirely different disease, with slow onset and different age and seasonal incidence. This condition is known as lethargic encephalitis and its chief incidence is on the brain stem, the patients suffering from asthenia, lethargy, and disorders of ocular movements such as strabismus, diplopia, nystagmus, and ophthalmoplegia. Other cases occurred in which the oculomotor signs were absent but which gave the clinical picture of acute paralysis agitans; in such cases the chief incidence was on the basal ganglia and, in particular, on the globus pallidus. In a third group of patients the force of the inflammation was spent on the cerebral cortex. These cases gave rise to considerable difficulty in diagnosis, especially in regard to the possible presence of cerebral tumor, cerebral abscess, or cerebral hemorrhage. The author here cites four cases, in all of which the patients were over 40 years of age. None of them presented cardiovascular changes suggesting cerebral hemorrhage; nor did the clinical history suggest this, but rather some subacute lesion—abscess or syphilitic thrombosis. In all, the Wassermann reaction of the cerebrospinal fluid was negative. The lessons which may be learnt from these cases are: (1) That patients of over 40, and even over 50 years of age, may contract the disease. (2) That a naked eye examination of a brain on a post-mortem table is not sufficient to discriminate between an ordinary cerebral hemorrhage and a hemorrhage which is only an accidental occurrence in the course of an encephalitis. When there are no obvious gross signs of disease in the cerebral arteries to account for a hemorrhage, it is essential that microscopic examination should be carried out in order to determine the cause for the blood extravasation. (3) We must look on the presence of thrombosed cortical veins associated with hemorrhage in the neighboring brain substances as strongly indicative of an inflammatory process. There is no reason to suppose that lethargic encephalitis is a new disease, but it may be assumed that endemic cases occur from time to time. The recent epidemic is of practical importance in that it indicates the possibility of encephalitis in cases of cerebral disease which present difficulties in diagnosis. At the moment we are not in a position to say what is the nature of the infection, or to point to any method of treatment likely to abort or cure the disease. The author's experience of the four cases cited leads him to think that operative intervention in the way of decompression is contraindicated, in spite of the presence of increased intracranial tension. As to prognosis we have at present little definite information. Microscopical study of pathological lesions in the author's cases showed the remarkable way in which the vessels of the brain react in this inflammatory process. The chief features observed were: (1) Perivascular infiltration mainly with small round cells; (2) small capillary hemorrhages which suggest a gradual oozing of blood through the damaged walls of small veins and capillaries; (3) thrombosis of small and middle sized vessels in different stages of organization; (4) ischemic softenings presenting the appearance of the hemorrhagic infarction which one sees in other organs; (5) subarachnoid hemorrhages and cellular infiltration of the leptomeninges; (6) general neuroglial proliferation; (7) changes in nerve cells, in some places showing chromatolysis and in others a process resembling that of coagulation necrosis.

4. Blood Pressure and Physical Fitness of the Soldier.—V. E. Sorapure points out the importance of the tonal changes evident in making a blood pressure observation by the auditory method, the significance of which, for want of a satisfactory explanation, is so often ignored by physicians. He describes the phenomena observed in a blood pressure observation and shows that the length of the first phase should be 20 per cent. of the pulse pressure, the second 40 per cent., and the third 40 per cent. Sorapure believes that the presence and relative lengths of these phases is of wider clinical significance than the height of the systolic pressure alone, or even that of the systolic and diastolic readings compared, since it is quite a common experience to find an obviously inefficient heart giving what is accepted as the normal systolic and diastolic blood pressure reading. The author remarks, however, that he has never seen a case such as this which showed all the phases in anything like the suggested normal proportion. An analysis of the blood pressure findings in a group of 769 soldiers during the twelfth week of training resulted as follows: (1) Comparison of the age groups showed that there was but little variation in the average readings; (2) the average systolic pressure was higher than in civil life, but it must be remembered that the tests were made at the end of a hard day's work; (3) the average diastolic pressure was more constant, not showing the same tendency to rise as the systolic; (4) the average pulse pressure was approximately 60 per cent. of the diastolic pressure; (5) the average period of the first phase was 20 per cent. of the pulse pressure; (6) the average period of each of the second and third phases was about 40 per cent. of the pulse pressure; (7) with the singular exception of age 25, ages 23 to 31 showed the highest percentage of men in whom all phases were present; (8) the extremes of pressure in each group were notable, indicating the wide range within which individuals vary, yet the average of each group was strikingly constant. In actual training it was found by experience that more could be expected from men between the ages of 21 and 31, and that those under 20 and over 35 required more careful handling. From these observations the author concludes that the most constant factor, the diastolic pressure, is for all ages somewhere between 70 and 90; that the systolic pressure should be about 50 or 60 per cent. higher than this; that the range of pressure between the two should be capable of differentiation into three different phases—the first, or first tonal, being 20 per cent. of the whole; the second, or murmur, being 40 per cent.; and the third, or second tonal, 40 per cent., which findings are characteristic of the fit man. A second group of 189 men was then analyzed; these men had all been invalided home from abroad, but none were suffering from organic heart trouble. Practically all showed, or had showed, evidence of autonomic disturbance of the

cardiovascular mechanism (D.A.H.). The features that were most marked in this group were: The very high percentage of the men who did not show all the phases and the greater instability of the diastolic pressure; in those who showed all the phases there was a remarkable variation in the relative proportion of same as compared with the first group; the best groups in this series, ages 29 and 36, compared most unfavorably with the worst, ages 37 and 39, in the first series. It is concluded therefore: (*a*) That the men who are less efficient than normal do not show the characteristic phases which prevail in the first series analyzed; (*b*) that those who are physically fit show these phases in the majority of readings; (*c*) that the result of this simple test is a factor worth considering in estimating the physical capacity of an individual. The practical application of this test takes but two minutes at most.

2. Bone Grafting in Gunshot Fractures of the Jaw.—William Billington, Arthur H. Parrott, and Harold Round point out that successful treatment of compound fracture of the mandible involves (1) osseous union, (2) functional occlusion, (3) avoidance of disfigurement. It is essential that firm osseous union should be obtained, even at the expense of deformity, otherwise the power of mastication is gravely impaired. Where there is a gap between the bony fragments of more than half an inch, osseous union is rarely obtained unless the fragments are allowed to approximate at the expense of normal alignment, or a bone graft can be successfully introduced, and in cases where the gap is wide the only successful means of treatment is by a bone graft. This is also indicated in cases where there is overriding and malposition of osseous fragments, or where mobility of the fragments from muscular action cannot be prevented by mechanical means—for example, short posterior edentulous fragments. Bone grafting in fractures of the jaw from war wounds has presented such difficulties that at first the attempt was given up. The deformity resulting from allowing the fragments to approximate, and the difficulty of fitting dentures was so great, however, that further attempts were made and the authors describe a technique which they now employ with such success that the graft rarely fails to heal firmly. Preliminary preparation is prolonged and may last for many months. An *x*-ray examination is first made, after which patient is anesthetized and the wound explored. Foreign bodies, teeth in or adjacent to the fracture, and loose fragments are removed, larger fragments of bone replaced in as normal a position as possible, and soft tissues drawn together. Provision must be made for sufficient drainage and access to raw surfaces inside the mouth. Sepsis is apt to be persistent while the wound is healing, and further operations may be necessary for the removal of sequestra and drainage of pockets. Dribbling of saliva from the mouth should be prevented by plastic operations, and careful attention must be paid to the maintenance of the patient's physical fitness. After all wounds inside and outside the mouth have healed, from four to six weeks should elapse before the bone-grafting operation is performed. Immediately before the operation, all dental fixation splints are removed from the mouth and at operation a skilled anesthetist is essential. A curved incision is made in the neck beginning one inch behind the extremity of the posterior fragment and ending one inch in front of the end of the anterior fragment. The incision commences and finishes about half an inch above the line of the lower border of the jaw and in the neck runs about one inch below that line. It is only by carrying the incision well below the jaw and raising a flap that sufficient soft tissue to envelop the graft satisfactorily can be obtained. Great care has to be taken in splitting scar tissue to avoid opening into the mouth, an accident which necessitates postponement of the operation. The unsatisfactory bed provided by this scar tissue constitutes one of the difficulties of this operation. The incision is deepened by cutting upward and inward until the lower border of each fragment is reached. The soft tissues covering the outer surface of each fragment are then raised for an inch away from the gap and turned up in the flap. Ends of fragments and fibrous tissue are carefully cut away, and finally each fragment is beveled by cutting away a flake of bone from its outer surface with bone forceps. All bleeding is carefully arrested and the bone graft prepared. After many experiments, the iliac crest was finally selected as the site from which to take the graft. This bone is tough and can be cut with bone forceps without splitting. Further, a graft can easily be obtained of any length or breadth, and the natural contour is approximately that of the jaw. The graft should be taken preferably from the same side as the operation wound, so that patient may lie comfortably on the other side. An incision is made over the crest, commencing at the anterior superior spine and extending as far back as required. Muscles are separated on either side and pressed back by retractors. With a Horsley's hand saw a graft two inches longer than the gap to be filled is cut; if a more curved piece of bone is needed the graft is made to include the bone between the superior and inferior spines. After removal of the bone, the muscles are sewn together with catgut and the wounds closed. The ends of the graft are then beveled, the beveled areas lying on the prepared outer surfaces of the jaw fragments. In this way the graft overlaps the gap by an inch at each end, which has the following advantages: a broad line of bony contact between the graft and fragments is provided, with increased prospect of speedy firm osseous union, and there is practically no risk of separation by subsequent manipulations. Experience has shown that the presence of foreign bodies, such as plates, screws, etc., militates against healing. The graft is therefore kept in place simply by sewing the soft tissues closely over the graft and ends of fragments by hardened catgut, and is thus surrounded with living vascular tissue and dead spaces are abolished. No drainage is employed beyond that of leaving spaces between the skin sutures to allow of escape of serum. No attempt is made to reintroduce dental fixation splints until the wound is firmly healed and the compound fracture converted into a simple one, which is usually in about two weeks. The final dentures should not be fitted for four or, perhaps, six months.

The Formation of Amputation Stumps for Voluntary Movement of the Arm Prostheses.—M. Borchardt offers a synthesis of the teachings derived from a long experience with the Sauerbruch-Staddler technique. The requisite conditions for the musculocutaneous canal formed in this operation are as follows: (1) The cutaneous tube must be composed of normal skin and placed sufficiently forward. (2) The sutures must be proximal as far as possible; union must be on the anterior aspect of the limb in order to avoid friction from the anterior branch of the prosthesis as far as possible. (3) The canal should be broad and short. (4) It should be perpendicular to the direction of muscular traction. (5) The canal should possess the greatest possible excursion when acted upon by the tunnelized muscles. In reference to these various desiderata, the writer shows what are the mistakes most frequently made in the technique of the operation. As to the formation of the cutaneous flap destined to tunnelize the muscles, he concludes that flaps made obliquely in relation to the axis of the limb are better for good implantation, on the one hand, on account of their nontransversal situation which already approaches the final transversal position, and on the other, on account of their semilongitudinal direction which assures a good vascularization of the pedicle. The excursion of the branches of the

prosthesis may attain eight centimeters for the biceps, while the triceps does not reach more than three centimeters. The complications and unsuccessful results (the reviewer has never seen a single case that could be called a really successful result among soldiers who had undergone this operation by Sauerbruch himself) are most commonly due to the following causes: (1) Partial necrosis of the distal end of the cutaneous tunnel; (2) Its total necrosis; (3) Inflammatory and suppurative processes within or in the neighborhood of the tunnel; (4) Persistent granulations in the tunnel; (5) Secondary sclerosis and occlusion of the tunnel and (6) Ulceration of the tunnel when the limb is used. Borchardt studies the precautions which are necessary to take in order to avoid these always possible complications. He does not approve of shortening the bones as this might hinder the fixation of the prosthesis. In high amputations, he proposes tunneling the pectoralis major as was carried out in a case of disarticulation of the shoulder, with, he says, a good result.

The Pathogenesis of Trophic Tissue Disturbances Following Lesions of the Nerves.—F. Breslauer defends the thesis that the trophic function of the nerves depends above all on their vasculonervous function. Some experimental work and some considerations on a subject of already rather old vintage, lead the writer to conclude that trophic disturbances are the result of the less of the vasodilating reflex function. They are usually accompanied by anesthesia.

Can Spontaneous Rupture of a Healthy Aorta Occur and How Does It Take Place?—F. Oppenheim studies this question in relation to a case in which the aorta was torn as the result of efforts at defecation, and ruptured into the pericardium. The patient had a glomerular nephritis. A most minute histologic examination did not reveal any changes in the aortic walls. Therefore, the rupture must have resulted from an internal hyperpressure. Experimental researches undertaken by the writer showed that the normal aorta, when submitted post mortem to an increasing hydrostatic pressure, ruptures at a point of election situated at its posterior aspect slightly above the sigmoid valves. But in comparing the necessary pressures for rupture of this vessel after death, to pressures which produce it in the living, it becomes evident that the required pressure is three or four times less in the latter. The writer gets around this difficulty by supposing that the aorta in the living is three or four times less resistant than in the cadaver, a supposition which, to say the least, is rather paradoxical and scarcely one to cause conviction to the scientific mind. It would appear most logical to suppose that Oppenheimer's patient possessed arterial changes which were not microscopically evident. As to predisposing factors of "spontaneous rupture," the writer first invokes the factors of hypertension, and afterward circumstances causing dilatation of the aorta at its origin, first of which in order of importance should be placed stenosis of the aortic isthmus.

Substitution of the Paralyzed Biceps by the Pectoralis Major.—G. Hohman, in a case of poliomyelitis which had resulted in paralysis and marked atrophy of the right arm, with laxity of the shoulder-joint and loss of all movement in the elbow, resorted to the following operation at one sitting: Scapulohumeral arthrodesis and fixation in abduction at an angle of 110°; a loop was formed by suturing certain tendons of the arm together (the writer's description is more than vague) and through this loop the tendon of the pectoralis was passed and sutured to that of the biceps which had been shortened by several sutures. It is quite impossible to determine from the writer's incomplete description whether or not he sutured the pectoralis to the block of flexor tendons. At the end of a fortnight the limb was mobilized and the following result obtained. By mobilization of the scapula a certain amount of extension of the arm could be made, while the forearm could execute energetic flexion. The arm could be used in eating and could execute little movements.

The Effect of Natural and Artificial Carbonic Acid Gas Baths on Cardiac Subjects.—E. Weber describes a procedure which allows one to follow and estimate the progress made in the circulatory functions under the influence of this treatment, by means of plethysmographic charts.

The Specific Treatment of Frank Pneumonia.—C. Klieneberger recalls the fact that frank pneumonia ends in a sudden crisis of resolution at the time when the antipneumococcic opsonic index undergoes an ascension, a fact proved by many laboratory researches. This fact leads to the hope that a certain amount of success may be derived from passive immunization. To obtain this end the writer has resorted to a polyvalent serum and thinks that he has been able to note happy effects by this treatment. The article is written in a critical spirit and the writer remembers the ordinary benignity of the disease which is recovered from "in spite of any treatment." Treated with serum pneumonia seems to have a quicker evolution, while the drop in temperature takes place by lysis instead of the usual crisis.

Salvarsan-Silver.—Gennerich has obtained good results from the exhibition of this product and finds that it is less toxic and more efficacious than other salvarsan products. A treatment of two and a half or three weeks is enough to obtain abortive sterilization of a primary local syphilis in the seronegative phase. A primary seropositive syphilis is also cured in a short lapse of time, while in secondary lues many cases become seronegative in from three and a half to four weeks, so that any future treatment becomes unnecessary. Cases of older infection require a more prolonged treatment, which should be combined with the iodides rather than with Hg.

Wiener medizinische Wochenschrift.

October 9, 1918.

The Blind of Warfare.—L. Schmeichler offers a paper containing a certain number of case histories which enter into the domain of the psychology of the blind of warfare, and also in the domain of their social usefulness. The relations with this category of wounded should be those of affectionate cordiality, and at the same time combined with a certain amount of humor. Contact of the hand on the arm or shoulder of the blind subject at once establishes a psychic contact which facilitates the relations. The writer insists on the serious psychic shock at the beginning and therefore an optimistic prognosis should be given to these men. The ulterior failure to produce an improvement in their sight will allow the physician progressively to lead the patient to accept his unfortunate situation, but this should not be until the time comes for finding an employment which will offer a social situation of the subject. It is important that the blind should learn only one trade because the maximum of efficiency can only thus be obtained, and this efficiency will always be inferior to that of a man in possession of his vision.

Wiener medizinische Wochenschrift.

October 16, 1918.

Experiments with the Blind of Warfare.—L. Schmeidler states that the profession of musician or tuner is not to be advised for blind subjects having no former musical instruction. In Austria the blind are given a small house with a little piece of land. From the viewpoint of their pension, usually a little increased by that coming from a decoration, these men receive between 2,200 to 2,400 crowns. A law is about to be put through increasing this amount to from 3,000 to 3,200 crowns. (In Germany this pension is a little higher.)

Le Presse Médicale.

November 21, 1918.

Action of Organ Extracts and Autolysates.—Roger, who has worked for many years on this subject, con-

tinuing the original labors of Brown-Sequard and Bouchard, announces some generalizations, as follows: the least toxic of all extracts is muscle extract. To kill a rabbit by injecting this extract the amount necessary per kilo of weight is equal to 90-95 gms. muscle. The extract must also be made by the cold process for heat destroys some of the poison constituents. Liver extract is much more toxic than muscle, although still weakly active. At the other extreme the most toxic extract is one made from the lung. A dose equal to 5 or 6 gms. of solid extract will kill. Why should foreign protein show such differences of behavior? Is it a matter of physical chemistry, a difference in the size of the molecules in virtue of which more of the smaller sort reach the blood? There is another theory, that of tachysynthesis, in virtue of which the defensive substance which neutralizes the toxic protein in the blood adjusts itself more readily to one substance than another. The term tachysynthesis means literally rapid tolerance. If a weak extract of lung is injected into a vein the body quickly becomes accustomed to it. The normal fatal dose is supported and even doses 3 or 4 times as strong. Hence the stronger extracts lose their power by acquired tolerance. At the same time the large colloid molecules when injected subcutaneously may traverse with difficulty the cellular planes. If we compare them with glycogen the latter is arrested in the cells of the liver, where it undergoes hydration and a breaking up into smaller molecules, those of glycose. Proteins and neutral fats undergo a similar alteration. Tissue enzymes break up the large colloid molecules and in the intestine this act makes possible the absorption. In the substance of the tissues the process is one of autolysis. Here, as in ordinary digestion, large molecules are broken up into smaller. The study of the intravenous injection of autolysates should be of interest. The author soon learned that an organ subjected to autolysis is less toxic than an intact organ. After standing for a given length of time the autolyzed organ is less toxic by a very high ratio—from 1 to 16 to 1 to 77 in some material tested. But physiological activities now become obvious, as, for example, when an autolysate of lung tissue was seen to have an action on the bloodvessels somewhat resembling that of adrenaline. Sputum which contains albumin can be made to show hypotensive property but albumin-free sputum is inert in this respect. Sputum of consumptives always contains albumin and may have a marked hypotensive action.

Journal de Médecine de Bordeaux.

November, 1918.

Influenza in Bordeaux.—Arnozan writes succintly on this subject. Whence came the disease? From Switzerland through repatriated prisoners? From Spain, which is not far away? From the fighting front? No one can tell. Perhaps from all three. It seems certain that repatriates from Switzerland are partly responsible, because cases could be traced directly to them. A few cases were in evidence in June and in July the number augmented. But not until the end of September could the malady be regarded as epidemic. The time was ripe for closing schools and colleges before the malady could spread but this step was omitted. The annual opening of the educational institutions at this period seemed to give the disease a push. It broke out everywhere. Prophylactic efforts were at once set in motion and apparently to advantage. All was done which could diminish collecting and crowding on the part of the public. The death rate began to decline from the first week in November and at time of writing is low, but a recrudescence is possible. Is this epidemic the same that flourished thirty years ago? The older was more contagious, for hardly any escaped. The current epidemic has spared many citizens, but is more murderous. The type shows much difference, for cerebral symptoms and empyema, so common at present, were but little in evidence in 1890. Pfeiffer's bacillus, credited as the exciting cause in 1890, is now relegated to the position of a cause of secondary complications. The pneumococcus was not much spoken of in the older epidemic and was present only exceptionally. When bronchopneumonia appeared in 1890 it was always streptococcic. In the older experience the mask was not thought of, which speaks volumes for the more deadly quality of the present epidemic. We thought more of the possibility of aerial transmission and less of the mouth to mouth transmission in the old days. Now all of our prophylaxis centers about preventing this mouth to mouth contagion. The germ is not visible outside the body and despite apparent examples, air borne transmission has not been proven.

Le Progrès Médical.

November 30, 1918.

Conception of the Febrile State.—Bernheim states that in fever there are two leading phenomena, acceleration of pulse and rise of temperature. Neither alone can constitute fever because tachycardia is a general symptom and hyperthermia is a general symptom. A temporary rise of temperature is not a febrile phenomenon, for this rise must persist over a certain interval. This persistence is due to the presence of some pyrogenetic agency which is responsible for what we call the febrile movement. The latter has a definite range based on the normal thermogenesis of the body which results in a temperature of 37° C. The range is ordinarily from 39° to 41° C. The most common of the pyrogenetic agencies is a microorganism or its toxic secretions. While certain organisms are pyretogenic themselves others are not, the latter including the causes of cholera, whooping cough and syphilis. The latter, when they do excite fever, are associated with other bacteria which are pyretogenetic. There are numerous organisms which can exist in the body without causing fever until they are roused to pathogenicity. Here belong the pneumococcus and typhoid bacillus. In organisms of this type not the organism itself but the toxic secretion must constitute the pyretogenous principle. There are, however, true fevers which are not of microbian origin and here belong such phenomena as milk fever, fever of dentition and perhaps certain fevers of endocrinic origin. That certain drugs cause fever may be explained by latent microbism, and this doctrine can of course be thought of in connection with the physiological fevers just mentioned. The unknown poison of influenza arouses the latent microbism of clinical grippe as shown in pneumonia and septicemia. Our only rational treatment of fever is the use of antisera for we know of nothing else which could possibly neutralize the pyretogenic agents.

Hygiea.

October 31, 1918.

Case of Cardiospasm with Dilatation of the Esophagus.—Lindstrom reports the following: Patient, male, 43 years old, ill 6 years with stomach symptoms. For past three years voluminous and persistent vomiting. Marked emaciation, present weight 78 pounds. Obstruction at cardia and notable dilatation of the esophagus above. Treated by gastrostomy and feeding through the fistula. Recovery of general health but patient still unable to swallow food most of which sticks in the gullet. Treatment with sounds without result. Radical intervention as follows: temporary closure of fistula and incision along left costal margin. Marwedel's incision then gave access to cardia. No scar or other evidence of past ulcer. The author then went through the peritoneum and the cardia was mobilized for its whole circumference. The stenotic portion of the esophagus up to the dilatation was now exposed and dilated digitally up to the admission of three fingers. The finger was pushed up through the cardia and stenotic portion. A cardioplastic operation followed which involved the cardia proper and the formerly contracted esophagus. A thick sphincterlike muscle ring 3-4 cm. above the cardia required division. There was no postoperative reaction and on the next day patient was able to swallow water and semifluid food, as eggnogg. On the tenth day the sound was removed from the fistula the latter soon closing spontaneously. An x-ray picture taken two months later, showed that fluid and semisolid food passed readily through the gullet. There was no tendency to contraction, as the largest stomach sound readily entered the stomach.

Book Reviews.

THE UNSOUND MIND AND THE LAW. A Presentation of Forensic Psychiatry. By GEORGE W. JACOBY, M.D., author of "Child Training as an Exact Science," Fellow of the New York Academy of Medicine, member of the American Medical Association, American Neurological Association, and New York Neurological Society, Consulting Neurologist to the Hospital for Nervous Diseases, the German Hospital, the Beth Israel Hospital, the Red Cross Hospital, and the Infirmary for Women and Children in the City of New York, etc. Price, $3 net. New York: Funk & Wagnall Co., 1918.

DR. JACOBY has endeavored to meet the demand for a book which will bridge the chasm between the legal point of view and the medical one in dealing with abnormal offenders, and has succeeded to a certain extent. His chief error, *i.e.* the insistence upon a purely material basis for all mental disorder, does not affect the book's value for the lawyer, or even for the general practitioner. We do not see how the lawyer or physician can fail to derive much benefit from this book. An interesting feature is the inclusion of several actual cases where the determination of the mental state was a matter of difficulty with a careful analysis of these cases and a full opinion. The book as a whole is of convenient size and a handy reference book when legal difficulties threaten.

WAR NEUROSES. By JOHN T. MACCURDY, M.D., Psychiatric Institute, Ward's Island, New York; Lecturer on Medical Psychology, Cornell University Medical School, New York; with a preface by W. H. R. RIVERS. M.D. (Lond.); Fellow of St. John's College, Cambridge. Price, $2.50 net. Cambridge: At the University Press, 1918.

AN unexpected and alarming feature of the Great War was the large proportions of nervous and mental diseases in the casualty list. The condition known as "shell shock" was first a curiosity, next a recognized disease, and finally a problem and a menace. This volume is an effort at studying the problem and finding a remedy. The author approaches it from a psychological standpoint, which is the only really intelligent one. He believes that fatigue is the chief cause, acting upon a neurotic constitution. Many illustrative cases are given and the book is a valuable one, although limited in scope. The space given to prophylaxis, we believe, could be enlarged advantageously.

THE HUMAN MACHINE, AND INDUSTRIAL EFFICIENCY. By FREDERIC S. LEE, Ph.D., LL.D. Dalton Professor of Physiology in Columbia University; President of the American Physiological Society; Consulting Physiologist to the U. S. Public Health Service; Chairman of the Sub-Committee on Fatigue in Industrial Pursuits of the National Research Council; Executive Secretary of the Divisional Committee on Industrial Fatigue under the Advisory Commission of the Council of National Defense. With illustrations. Price, $1.10 net. New York: Longmans, Green & Co., 1918.

PSYCHOLOGY and physiology are beginning to take their merited place in economics. Manufacturers are beginning to realize that in their calculations they must take into account the human machine with its limitations and potentialities. Thus the Government in its press of war work found it advisable to give its clerks two recess periods during the day, besides the lunch hour. In this little book are discussed some of the factors which enter into industry, such as fatigue, capacity, night work, food and so on. The author has written an exceedingly instructive little book, one which can be read with profit by anyone who employs labor or is responsible for the health of workmen.

MENTAL DISEASES. A Handbook Dealing with Diagnosis and Classification. By WALTER VOSE GULICK, M.D., Assistant Superintendent, Western State Hospital, Fort Steilacoom, Washington. Illustrated. Price, $2.00 net. St. Louis: C. V. Mosby Co., 1918.

WE do not see how this book can be of any assistance to the physician. In 139 small pages the author has endeavored to discuss the whole field of mental disorder, quote cases, and give pictures of 35 patients. Naturally the book takes on the form of a compend, and a not too accurate one at that. One must have a wonderful gift of condensation to describe psychogenic neuroses, for example, in something like 700 words, but this author has attempted it. Defective states are given about 200 words. In short, the book impresses us as an effort to squeeze a quart into a pint pot—an impossible feat.

INTRODUCTION TO ORGANIC CHEMISTRY. By JOHN TAPPAN STODDARD, Professor of Chemistry in Smith College. Second Edition. Price, $1.50. Philadelphia: P. Blakiston's Son & Co.

THIS little book should prove serviceable to the beginner in organic chemistry. The author presents the subject very clearly, and avoids too much detail. Fundamental principles are presented, and the student is gradually led into the desirable habit of "thinking in chemistry." The book makes no pretence to be more than an "introduction"; and in conjunction with a modern text-book and laboratory work, it should smooth the student's path and make a pleasure of what so many find difficult and confusing. The book is well arranged and is of a handy size.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints. Vol. XXVIII. New York, 1918.

THIS publication is a paper-bound collection of reprints which have appeared in various medical journals during 1917. The contents are classified under the headings of "Pathology and Bacteriology," "Physiology and Pharmacology," "Chemistry," "Experimental Surgery," "Experimental Biology," "Papers from the Hospital of the Rockefeller Institute," "Animal Pathology." These Studies appear serially at irregular intervals. The present volume comprises 661 pages, including an index of both authors and subjects. The name, date, number, and page of the journal in which each article originally appeared are printed above the title. The papers are accompanied by numerous cuts, charts, and plates. The range of subjects is wide, varying from pure research problems to topics of a very practical clinical character.

PRINCIPLES OF BACTERIOLOGY. By ARTHUR A. EISENBERG, A.B., M.D., Cleveland, Ohio; Director of Laboratories, St. Vincent's Charity Hospital; Demonstrator of Pathology, School of Medicine, Western Reserve University; Visiting Pathologist, St. John's Hospital; Visiting Pathologist, Lutheran Hospital; Fellow American Medical Association. Illustrated. Price. $1.75 net. St. Louis: C. V. Mosby Company, 1918.

A TEXT-BOOK for nurses is not easy to write successfully, for it must contain nearly as much information as is given to medical students, with the restrictions that the language must be as non-technical as possible. nothing essential must be overlooked, and the author must not assume any correlated knowledge in other branches. Dr. Eisenberg has written a manual of bacteriology which fulfills all these conditions, and hence is to be congratulated. The fundamentals of the subject are concisely and clearly presented, and in 187 small pages he has marshaled a vast amount of information. Indeed, the volume would not be out of place in the library of the general practitioner.

DISPENSARIES: Their Management and Development. A Book for Administrators, Public Health Workers, and All Interested in Better Medical Service for the People. By MICHAEL M. DAVIS, JR., Ph.D., Director of the Boston Dispensary, and ANDREW R. WARNER, M.D., Superintendent of Lakeside Hospital, Cleveland. Price, $2.25. New York: The Macmillan Company, 1918.

THIS monograph traces the history of the dispensary which culminates in the statistics of the dispensaries of the day as limited to the United States. Dispensary patients are next analyzed, as well as the medical and administrative organization and the social service factor. The technique of operating dispensaries, out-patient departments of hospitals, and other ambulatories is next given. The final section deals with the interrelations of dispensaries and practising physicians.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 23, 1918.

EX-PRESIDENT DR. FREDERIC E. SONDERN IN THE CHAIR.

Committee to Consider Workingmen's Compensation.—Dr. E. ELIOT HARRIS presented a resolution to the effect that inasmuch as the New York State Association for Labor Legislation and the Merchants' Association had prepared a new bill amending the Workingmen's Compensation Law for presentation at the coming session of the Legislature, a copy of which had been submitted for the consideration of the Medical Society of the County of New York, a committee be appointed to consider this bill. This motion was carried and a committee appointed consisting of Dr. Eden V. Delphi, Dr. William S. Gottheil, Dr. Daniel S. Dougherty, the chairman of the Committee on Legislation ex-officio, and the Chairman of the Committee on Public Health ex-officio.

The Office of the Chief Medical Examiner; Its Relation to the Public, the District Attorney's Office and the Medical Profession.—Dr. CHARLES NORRIS read this paper, in which he stated that a legislative act, which became law April 4, 1915, established the office of Chief Medical Examiner and thereby abolished the office of coroner. The functions of the office were entirely investigatory, namely, the determination of the cause of death, a medicolegal investigation which might require the aid of refined bacteriological and pathological methods and familiarity with gross pathology which came only to those who had had a long and varied experience in this important field of practical medicine. A review of the sections of this act of the legislature showed that they determined when an autopsy was necessary and when a case might be closed on examination—and it also required that post-mortem records should be dictated on the spot to a stenographer. In the opinion of the speaker the law was admirably drawn up for effective work. Under this law the chief medical examiner might appoint and remove such deputies, assistant medical examiners, scientific experts, officers, and employees as might be provided for pursuant to law. In the past no decent provision for the chemical examination of the viscera of cases of known or suspected poisoning existed. The investigatory functions of the chemical laboratory of the Chief Medical Examiner's Office were of the greatest value in determining the cause of death in suspected cases of poisoning from alkaloids, metals, etc. The proper presentation of the evidence of poisons before the courts was a matter of the utmost importance in many cases of homicide, suicide, and abortion, and even in accidental cases of poisoning. In the past, for the want of proper legal presentation, many cases have been lost in the courts. Chemical examination of the organs, even in cases of poisoning, where there was suspected criminality, should be done in every case. This work had been done for the Medical Assistant of the District Attorney of New York County since this office was created, and previous to this time, for a few of the coroner's physicians who asked for this departmental courtesy, by the pathological department of Bellevue Hospital. During the recent gas epidemic the spectroscopic examination of the blood of cases of asphyxiation and various tests for carbon monoxide were performed by the assistant medical examiners and by the laboratory. The necessity had been recognized of preserving evidence for court presentation in cases of suspected homicide through gas asphyxia, and they had adopted the method which enabled them to do this. The duties to the public were in the main prompt service and courtesy, the issuance of death certificates, the performance of autopsies in accident cases to protect the civil rights of the relatives of the deceased in one case and in the other insistence on the performance of post mortems to protect private and hospital physicians. It was important that the medical examiners should testify only to matters of fact and evidence, not on opinion, except as it might be asked for on either side. Dr. Norris said it was his aim to have the office of medical examiner avoid the numerous errors of the past which necessitated re-examinations or so-called secondary or fresh autopsies which entailed exhumation in accident or homicide cases, at large and unnecessary expense.

In speaking of the relation of the office to the District Attorney, Dr. Norris stated that the office sent to the District Attorney the reports of deaths of all cases of homicides, suicides, cases of poisoning, and all suspicious cases. They included the chemical reports and any evidence indicating criminal negligence in accident cases and copies of the testimony taken under oath. The office, unlike the coroner's, held no inquests. This work was performed by the grand jury, the magistrates and the district attorney. The medical examiner and his assistant medical examiners might administer oaths, and take affidavits, proofs, and examinations as to any matter within the jurisdiction of the office. Recently in a hotel room a woman was overcome after cyanide disinfection of one of the rooms. An autopsy was made and evidence of cyanide poisoning was found by chemical tests. The agents of the disinfecting company in this case were, in the writer's opinion, distinctly at fault in allowing people to enter the room before it had been sufficiently ventilated. It was a function of the office to see that appropriate measures were taken to force companies to exercise more care. Steps were being taken to include chloroform among the articles which could not be dispensed without a physician's prescription. Dr. Gettler and the writer had been able to develop a method for the detection of salvarsan and its substitutes, and were able to state that this method was valuable in suspected cases. Briefly, the policy of the office was to bring out all the facts, medical, pathological, or chemical, and to present all such evidence in proper fashion, and at the same time to avoid the danger of looking at facts through the spectacles of theory.

The prosecuting branches of the office were in the hands of the District Attorney and the Police Department. It would be seen that there was grave and urgent reason for the separation of this office from the police and that of the District Attorney, and that this office should not be a bureau of these departments, but a separate department of medicolegal inquiry. For all practical purposes, however, the three departments must work hand in hand. The medical examiner's department, on the other hand, was subject to the jurisdiction of the Department of Health, which might, from time to time, make rules and regulations affixing the times of rendering, and defining the form of returns and reports to be made to said department by the office of the chief medical examiner. In all cases of death the office of the chief medical examiner was required to conform to such rules and regulations. The medical work of the office was performed by eleven assistant medical examiners. One of these was an acting deputy who helped the chief medical examiner at night. The Manhattan office in ten months had handled 5280 cases with four medical examiners; the Brooklyn office during the same period had handled 3322 with only two medical examiners. Dr. Norris then described the difficulties of performing the work with the limited amount of help and showed that the physicians received only $3,000 a year and about half of this was required to pay for their transportation in attending to their cases. Furthermore no provision was made for vacations, the medical examiners being on duty every day of the year. The speaker's point in bringing out the detail of the routine life of the examiners was to testify to their extreme good nature and the high sense of civic duty that they exhibited. While there was provision for autopsy work in Manhattan, in the other boroughs it was performed with the greatest difficulty. While the department was well equipped, or at least had made a good commencement in chemical and toxicological examinations of the cases coming under their observation, the same could not be said for what he termed the other scientific branches of the department, namely, the microscopical and bacteriological examinations. They were forced in the Borough of Manhattan to call upon the pathological department of Bellevue Hospital for aid in these examinations. In the last budget they had asked for the appointment of three pathologists and a laboratory assistant and a laboratory helper. This request was not granted. At the present time they had

no facilities for performing serological reactions. The condition might be accurately described as disgraceful. It was not possible to properly perform the work of this office in the Boroughs of Queens, Bronx, and Richmond, where autopsies were mostly held in undertaker's shops. The examiners in the offices had no way of improving themselves along the line of their work, yet to perform the work of the office properly the medical examiner must have high qualifications. It was impossible at the present time to obtain men properly qualified for the position of medical examiner. After describing the various qualifications which he had found were essential for the proper performance of the work, Dr. Norris called attention to the importance of the questions which confronted medicolegal inquiry. A matter of grave importance in the medicolegal and criminal investigation of cases of abortion and suspected abortion dying in the various municipal and private hospitals, and more especially in the various sanatoria and physicians' offices of the Greater City of New York, was that the attending gynecologists and surgeons and their respective staffs and internes were singularly unaware of their responsibility to the prosecuting authorities in regard to the preservation of the pathological material of such abortion, namely, the curettings and, in some cases, the uterus removed by hysterectomy. He felt that if the attention of the medical profession were called to this subject there would be a prompt improvement of this deplorable situation.

Dr. J. P. Davin asked what the expense of conducting the medical examiner's office was as compared with that of the coroner's office.

Dr. Norris replied that the last coroner's budget was $157,000, while that of the Medical Examiner was $90,000.

Dr. Davin expressed the opinion that there was no reason why the medical examiner should not have as much money with which to run his office as the coroner had had.

Dr. Norris said that the medical examiner would like to have as much or more than the coroner had had. He needed as much in order to run the office efficiently.

Dr. Davin recalled that he was the first physician in the city to call attention to the advisability of having a medical examiner instead of a coroner. He asked whether a doctor was expected to send in the curettings in a case of suspected criminal abortion. Some months ago a bulletin of the Department of Health had called attention to the fact that doctors should save curettings from cases of abortion and he had gained the impression from that article that if a doctor did not do so he was *particeps criminis*.

Dr. Norris stated that there was no law requiring a physician to send the curettings from a case of suspected criminal abortion to the office of the medical examiner, but it was advisable for the physician to save such curettings in case they should be called for.

Two Hundred and Fifty Major Operations Under Local Anesthesia.—Dr. Joseph Wiener read this paper. (See page 135.)

Dr. Martin W. Ware said he felt a little awkward in opening the discussion, because he thought it would be made much simpler for him if he had had predecessors and then he could merely have confirmed everything they said. He had been associated with Dr. Wiener and could substantiate everything he had said. He would not have the impression left that this was an exploitation of any one drug, as apothesine, for his experience had been with novocain and he had obtained just as brilliant results with that drug. He recalled that twenty years ago he had listened to a discussion before this society, when one of the members who was still with them had said that there was no such thing as local anesthesia, that one always found that the patient cowered under the operation, and that idea had a considerable following. To express this idea the expression "anesthesia dolorosa" was coined, which implied that local anesthesia was always accompanied by a great deal of pain. The success of local anesthesia depended upon the suffusion of the anesthetic agent through the tissues and particularly upon the infiltration of the various planes. At the slightest indication of pain on the part of the patient one should not be diffident, but should inject more of the anesthetic solution just as one would push ether to get the patient under the anesthetic. Dr. Wiener's remarks were of interest in connection with what had been done in the war area. He regretted that Dr. Gibson was not here to report on the operative work done under local anesthesia in the war zone. Dr. Cushing likewise had achieved great victories in performing operations on the head and brain under local anesthesia, and in lung surgery the largest operations were performed under local anesthesia by blocking off the nerve supply to the operative area as the nerves emerged from the spinal cord. When this was done the lung itself was very amenable to operative procedures. Dr. Wiener had omitted to mention the point that was a stumbling block to the more general use of local anesthesia. A patient often came into the hospital thinking that the visiting surgeon was going to perform the operation; when he was under the general anesthetic the house surgeon might operate without the patient being any the wiser, but if the patient was given a local anesthetic the visiting surgeon might have to perform the operation himself, and at this the house surgeon demurred because he was not getting his quota of operations. This was a stumbling block in the way of carrying out local anesthesia properly. Dr. Ware again confirmed all that Dr. Wiener had said and added that the idea could no longer be held that local anesthesia was only a resort in emergencies; its application was just as broad as that of general anesthesia.

Dr. John H. Branth expressed the opinion that local anesthesia should be applied much oftener in surgical operations, especially where the outer tissues of the body were concerned. He related an experience he had had some twenty-five or thirty years ago, when he was troubled with an intense toothache and could not reach a dentist. He applied cocaine to the hollow of the tooth, but without relief. He then used a hypodermic needle. Owing to the awkward angle it broke off. He removed the fragment and with a new needle introduced another dose of cocaine at a greater slant. He then applied the forceps and pulled the tooth, a painless extraction. However, he suffered the toxic effects of the cocaine. Later he visited instrument stores to buy an angular needle, but no such needle was known at the time. He then devised one which was put on the market. Rocking the tooth loosened the pericementum. As a rule dentists did not *pull* teeth, but in the hurry necessary under nitrous oxide anesthesia, they broke out the tooth by fracturing the alveolar process. His procedure removed the tooth clean from the socket, and no ulceration or sloughing followed. The tooth cavity was closed in a few days. He had not succeeded in persuading dentists to adopt this plan. Dr. Branth related an instance in which he had performed a difficult extraction in cases upon which several dentists had refused to make the attempt by the use of cocaine anesthesia. The proper anesthesia by a solution of cocaine was induced by infiltration with internal pressure in the tissues, which was brought about by very dilute mixtures, so weak indeed that one might think it pure water, though it was very bitter to the taste. He took a small crystal of cocaine, like one of granulated sugar, about double the quanitity of eucaine on the point of a penknife, and half a wine glass of warm sterile water. This he injected with a long needle. Anesthesia was complete within a few seconds. The solution was made fresh for each case. By such a solution the speaker had removed not long ago a large cancerous growth from the neck, which was of such a size that it interfered with respiration and deglutition. This patient wished for two weeks of life in which to adjust his financial affairs. He had been treated with *x*-ray. He lived two months from the date of the operation. He was supposed to have tobacco heart and therefore local anesthesia was the only resort. After being on the operating table an hour and a half he got up and walked up one flight of stairs to his room in the hospital. His heart became regular at once after the removal of the tumor, the irregularity having no doubt been caused by pressure on the pneumogastric and sympathetic nerves. Under general anesthesia this patient would have had a very small chance of surviving the operation. Later the cancerous affection attacked the carotid artery and the patient really died from hemorrhage. The chief trick in the cocaine anesthesia was that the tissues were infiltrated to the

extent of internal pressure—ballooning. The tissues would turn white, becoming anemic, and the operator could see with his eye the field unobscured by blood. The extremely diluted solutions appeared safe, while the concentrated mixtures were fraught with danger. In circumcision he put a rubber band around the penis to prevent the cocaine from escaping to the body or trunk. The deaths resulting from cocaine injections reported in the medical literature all followed the use of the customary 4 to 10 per cent. solutions. Dr. Branth described his own experience during an operation for direct hernia which Dr. Bodine performed on him some two years ago. He said that the preliminaries, such as scrubbing the surface, washing with alcohol and ether, and finally painting with iodine, produced a glow and burning of the surface, so that he could not distinguish the cutting of the knife. His senses were at such a high pitch that he could hear (perhaps it was imagination) the passage of the knife, as though the skin were thick like sole-leather; he felt that something was being done on his abdomen, but there was surely the absence of pain during the operation.

Dr. Samuel Floersheim described his experience with local anesthesia from the standpoint of the patient as well as that of the surgeon. He stated that he came before the society in the threefold rôle of a doctor who had been operated on for appendicitis under local anesthesia, a doctor who had talked to his patients the morning following the operation, and a witness regarding the painlessness of the operation. The opening of the abdomen was entirely painless. In delivering the appendix and in doing the ligating the appendix on its mesentery there was slight pain, but none when the appendix was cut and none when the abdomen was sewed up. The operation had taken thirty to thirty-five minutes and he felt no further pain when he was put back to bed. He had a good night's rest following the operation and a good day, but the following night he had some gas pain, which was probably due to the fact that he was not prepared for the operation and had eaten quite heartily the day before. He sat up between the second and third day and the fourth day walked about the room, going home on the sixth day. If he should have appendicitis again he should choose to be operated on under local anesthesia. As Dr. Wiener had said they usually gave one-half grain of morphine before the operation, but as he had a dislike for morphine he desired to avoid taking it. Finally the nurse injected one-quarter of a grain in the left thigh and the slight discomfort that he experienced he attributed to the effects of the morphine rather than to the operation. Since that time he had worked with Dr. Wiener on a number of cases and felt sure that these patients were very comfortable and that they were more frightened than hurt. The speaker then reported a case to illustrate how extensive an operation could be performed under local anesthesia. This patient was a woman 62 years of age, operated on last September. When the speaker first saw her she had been vomiting for four days and refused to have anything done but to take a little medicine. Examination showed that she had what appeared to be an annular carcinoma of the rectum. She was persuaded to submit to an operation for artificial anus under local anesthesia. An incision was made, through the left rectus muscle which finally reached from the umbilicus to the sympysis pubes. On opening the abdomen it was found that the patient had a large double multilocular mass involving the sigmoid. When this mass was delivered, it was found that there were three mases occluding the sigmoid and that a portion of the same mass involved the cecum to which it was firmly attached and most difficult to separate from, and followed the course of the ascending, transverse, and descending colon, and was bound by two bands around the sigmoid as well as being attached in many places to the great omentum. Finally the entire mass was dissected loose and found to be ten or eleven inches in diameter. The growth was reported to be a pseudomucinous cyst of a rare variety, which was non-malignant. The abdomen was closed without drainage and the patient said she felt very well. The next day her bowels moved easily, painlessly and without medication, she passed much flatus and within six or seven days she was up. In ten or twelve days she was performing some light duties. This operation was performed in the patient's home, in a tenement kitchen, as patient refused nearly every suggestion advanced and absolutely refused to leave her home even under pain of the most serious outcome.

Dr. Samuel C. Gant said he had heard many papers on local anesthesia but this was the most direct and practical he had yet listened to. The method of employing local anesthesia was very simple but for some reason general surgeons did not employ it. He seventeen years ago reported before this Society a very large number of abdominal and anorectal operations, including colostomies, appendicostomies, and colopexies performed under local anesthesia. Perfect technique was essential to the production of complete local anesthesia and the average surgeon failed to develop it. One feature he had observed in his rectal work was that hemorrhage seldom followed local anesthesia operations. In hundreds of rectal operations he had not had a hemorrhage and this he attributed to local anesthesia, since there was no vomiting or straining as after ether which often caused dangerous bleeding. He employed one-eighth of one per cent. eucaine which never failed to produce complete anesthesia within ten seconds when infiltration was properly made. It was a question whether in ten years from now we would not laugh at a surgeon who used general anesthesia in many types of operation in which it was now employed. Anesthesia was painlessly produced by injecting the solution between the skin layers and afterwards in the deeper tissues until they turned white which indicated anesthesia. Many surgeons had asked him whether his fees were as large for local as for general anesthesia operations and he said they were larger.

Dr. H. R. Conway Gibbons stated that he had been interested in cocaine anesthesia ever since it was first introduced into this country, as it was in old Bellevue Hospital Medical College by Dr. Charles Stedman Bull acting for Dr. Henry B. Noyes, Professor of Ophthalmology in that school, who was abroad for his health which had been overwrought through a most exacting practice, both private and public, as well as his teaching. Dr. Noyes had written to Dr. Bull of a young medical man's observations through his experiments of chewing coca leaves which anesthetized his tongue, first on one side and then on the other, depending upon which he kept the chewed leaves in contact, and he observed a like effect on the buccal mucous membranes. It was then but a step for this patient experimenter to test the active principle of the leaves—the alkaloid cocaine—which was in time tried on the mucous membrane of the eye with a delightful anesthesia of the parts, making them insensitive even to cutting. The speaker's brother, Dr. P. J. Gibbons of this city, was a student at Bellevue at the time and communicated with him at once at Pittston, Penna., where he was actively engaged in practising general surgery, and the eye, nose and throat as a specialty. On the day following the speaker removed painlessly under the influence of cocaine a piece of steel that was embedded through the cornea and into the iris of a young man, John J. Patten, a machinist, who afterward was Park Commissioner of this city. This began his experience with cocaine which he used freely in nose and throat surgery. It was used especially in urethral surgery, however. Dr. Otis had asked the speaker over and over again to write a paper on his experience, much of which he knew about, as did his successor, the late William K. Otis. He regarded but few operations as belonging to the category of capital or major operations; on the contrary, he believed that the teaching of Dr. Hayes Agnew's method of defined or layer dissection, the anatomical "Keys to Operation" by Frank Hastings Hamilton by knife cutting methods, and the scissors method of dissection taught and demonstrated by Thomas Addis Emmet and Jenks of Detroit, had relegated to the dead past any such term as "capital" or "major" operations and he thought these terms no longer possessed the old time hoodoo effect in class room lore. Whatever else of the mysterious seemed to hover about the classical quotation "capital" or "major" operation in brain or spinal surgery was dethroned by the late Dr. Frank Hartley and his assistants in the New York Hospital in the introduction of the electrical engine as perfected by Dr. Charles McBurney, while Dr. Percy Watson of Jersey City and Dr. John A. Wyeth of

New York had made amputation of the hip quite a simple affair. Dr. Carl Koller of New York was the discoverer of cocaine anesthesia in eye surgery, and he had often expressed himself as very sorry for this discovery because of the misery it had occasioned through its irregular use, much of which irregularity had been, and perhaps still was, due to the careless method of the members of the medical profession in handling and prescribing this useful drug.

Dr. WIENER, in closing, expressed his gratitude to those who had discussed the paper and emphasized the fact that in many instances the life of the patient depended upon the kind of an anesthetic employed. He was perfectly in accord with Dr. Ware in not wishing to leave the impression that apothesine was the only drug that produced a satisfactory local anesthesia. Novocain was most excellent: he did not claim that apothesine was better than novocain, but it was equally as good, was made in this country, and the supply was unlimited. In the light of his experience the action of the two drugs was identical. Cocaine had been brought up in the discussion. He did not use cocaine and one could not do the work he had described with cocaine as it could not be given in such large amounts. He had given apothesine in doses of 10, 12, or 13 grains without unpleasant results. As a preliminary he used morphine, giving one-half a grain in two doses, and this he considered a very essential part of the procedure. If a patient asked to be operated on without this preliminary dose of morphine he demurred. At first he was afraid of using too much morphine, but with the exception of Dr. Floersheim, and a girl of fourteen years, all of his patients had received the one-half grain before the operation. In these two instances one-quarter of a grain was administered. The one-half grain was given in two doses of one-quarter grain each at an interval of forty-five minutes. The interval was important because if a patient had an idiosyncrasy for morphine it would be discovered before the large dose was given. In order to use local anesthesia successfully one must have experience with it. Braun, in a work published in 1914, had three or four pages on appendicitis, in which he advised strongly against local anesthesia, yet the speaker in this paper had reported 115 cases of appendicitis operated on painlessly by local anesthesia. With the mathematical precision of the German mind Braun had devised needles of different lengths by which to reach each layer of the abdominal wall, and when he failed of success by this method he made a sweeping condemnation of local anesthesia; he used no anesthesia in the mesenterolium. Dr. Floersheim had referred to paleness and faintness during the operation. The paleness was almost regularly present, and whether it was due to the morphine or the adrenalin he was unable to say. He had neglected to mention that he gave one c.c. of pituitary extract (subcutaneously, never intravenously) on the day after the operation to prevent tympanites. This was followed a half hour later by a high enema. After this treatment, in almost every case gas was passed within twenty-four hours; this was important for the comfort of the patient and the prevention of complications. His oldest patient was a woman 91 years of age who was operated on for strangulated hernia. It was difficult to make her believe that the operation was completed as she experienced no pain. She lived two years afterward. This was no unusual experience, as many of the patients left the table perfectly comfortable and laughing and joking. The patients operated on under local anesthesia were evidently perfectly satisfied as they sent others who chose this form of anesthesia in preference to general anesthesia. When he went into a private family to operate by means of local anesthesia he always took an anesthetist to adminster a general anesthetic if it should be necessary, but this had never occurred. He had also found that he could get a satisfactory anesthesia with a weaker solution than the one generally used. In two instances he had operated for appendicitis after using one-third of one per cent. apothesine. The only difference this change in the technique made was that he waited a little longer after giving the injection before cutting. Dr. Gant had expressed wonder that more surgeons did not use local anesthesia. This subject was brought up before the New York Surgical Society and the discussion showed that the use of local anesthesia imposed a greater strain on the surgeon. Some of the men stated that they were exhausted after operating on a patient under local anesthesia. The objection was also made that it was more tedious. It did take a few minutes longer but it was well worth while. He agreed with Dr. Gant that local anesthesia was the anesthetic method of the future.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 14, 1918.

DR. HERBERT M. WILCOX IN THE CHAIR.

Bronchiectasis Secondary to Obstruction of the Bronchi by Tuberculous Lymph Nodes.—Dr. WALTER LESTER CARR reported this case and presented the specimen and microscopic slides. He stated that the patient was a female infant, 1½ years old, born in this country, of Italian parents. No history was obtainable. On admission the child weighed 13 pounds 7½ ounces. The child was quiet and apathetic, the head large and square and the fontanelles closed. The mucous membrane of the nose was swollen and showed a few crusts. The child had eight incisors and four molar teeth, the upper incisors being broken close to the gums. The mucous membrane of the mouth was pale. The tongue was not coated. The pharynx was injected and the tonsils enlarged. The chest showed a rachitic rosary with depression at the lower part of the sternum. Examination of the lungs showed the percussion note normal anteriorly; posteriorly there was a slight dulness of the lungs at both bases. On auscultation coarse mucous râles were heard in the lower part of the lungs both anteriorly and posteriorly. The râles were very coarse on coughing and on deep inspiration. The voice sounds were not changed. These signs gradually increased. The percussion note posteriorly over both lungs became more dull as far as the anterior axillary line and from the scapula to the spine. Dry, coarse râles were heard all over the bases, also fine crepitations and mucous râles. The bronchial voice and bronchial elements increased more on the left side. Dry crackling râles were heard in the right lung anteriorly at the base. Examination of the heart showed the point of maximum intensity in the fifth intercostal space, 5 cm. from the midsternal line. The right border was in the fifth intercostal space, 2 cm. from the midsternal line. The sounds were of poor quality, the first sound being muffled and the second slurring. No distinct murmur was heard, although there was a suggestive systolic thrill at the apex. The liver was 3 cm. below the costal margin. The spleen was not palpable, but later became enlarged. The lymph nodes were palpable in the groin and in the axilla. The urine was negative. The temperature on admission was 99.5 deg. F., with variations of a degree and a half every day; it was often subnormal. Child lost in weight and then gained, only to lose again. The tuberculin skin test was positive. The *x*-ray plate of the chest showed a shadow at the base of the left lung, with peribronchial thickening at the hilum. The right side was not so well defined.

Dr. JOHN LARKIN said that he had not heard Dr. Carr's preliminary remarks, but he would like to say something from the standpoint of the pathologist in relation to atalectasis, not only in reference to the condition in children, but also in adults. He recalled this case very well clinically. A tentative diagnosis of tuberculosis was made, although the child was examined by Dr. Carr and the physicians of his staff, who found no definite manifestations of tuberculosis. In general adenopathy, other nodes, the cervical or the inguinal, were involved, but one could not make out any general condition of lymphatic involvement. There was no involvement of the abdominal lymphatics, so the diagnosis of "probable tuberculosis" was only a tentative one. There were pulmonary signs which pointed to obstruction in the lower bronchi, and the fact that the child suffered more from pressure symptoms would seem to lead to the diagnosis of obstruction of the bronchi rather than to general lymphatic involvement. When

the case came to autopsy the conditions found were those described by Dr. Carr. It was very common for the pediatrician to observe a condition of general adenopathy, sometimes giving rise even to sudden death, and from this specimen one might get a good idea of why death occurred in such cases. There was a slow obstruction of the bronchi, more commonly of the lower bronchi, either finally causing a complete obstruction, or else setting up a pneumonic process that eventually ended in death. When one came to study the pathological anatomy he found that it was not of the acute type, but represented rather a process of repair. From the specimen one got an idea of the great amount of obstruction, and noticed that there was a considerable amount of repair going on, or an attempt on the part of the body to protect itself, and the repair was most marked when the specimen was examined microscopically. There was no general adenopathy, except the lymph nodes at the bronchi were sufficiently enlarged to cause pressure at the hilus. If one wanted to trace out the anatomical relations of the lymphatics to the bronchi and to the lungs he would see that there were two sets of lymphatics, one going to the bronchial tree, and the other to the visceral pleura. In this case the cross section of the lymphatic nodes showed that no great amount of caseation had occurred, but there was very marked hyperplasia. There were present all the features of a bronchiectatic process going on in a slow but systematic manner, and a rather symmetrical arrangement of the lymph nodes around the bronchi; these had gradually enlarged, causing a slow constriction which had resulted in a tremendous amount of dilatation of the bronchi. Both lungs showed ordinary bronchiectasis and areas of lobular pneumonia. The mucous membrane lining the bronchi was perfectly preserved, and there had been no destruction of the epithelium. A considerable distance from the bronchi there was a condition of peribronchial pneumonia, in some areas leading to a confluent lobular pneumonia. The lung showed no tuberculous process, nor did the other viscera, the tuberculous involvement being confined to the region near the hilus. Where there was partial obstruction by a foreign body or pressure by bronchial lymph nodes, we had a secondary condition which led ultimately to bronchiectasis. While the child might apparently recover from the lung process, a chronic pulmonary condition would persist, accompanied by a condition of bronchiectasis, and such individuals were always chronic invalids. In the adult there were other conditions analogous to those found in the child and, while these might not be interesting to the pediatrician, it might not be amiss to relate that in the adult there might be a similar condition, due to pressure on the bronchi, either pressure by a foreign body, or from a bronchial growth at the bifurcation of the bronchi. One might get pressure from a mediastinal growth. This we saw in lymphatic conditions, as in the leucemia of Hodgkin's disease. Again we might have pressure caused by an aneurysm. It might not, however, have reached that degree where we would have connective tissue processes going on in the lung itself. It was well to keep in mind these forms of obstruction caused by an adenopathy unassociated with tuberculosis which might cause an ordinary bronchiectasis, with or without interstitial changes in the lungs. In making a diagnosis in a case of this kind it was well not to limit oneself to a consideration of the physical signs alone, but to direct one's attention to the general systemic condition to which the children were subjected.

Dr. CARR said he had presented this report because they had examined the child and found it difficult to say how far the lungs were tuberculous. This case was not one for operation, but it brought up the question whether in somewhat similar cases operation might be considered advisable, that was whether it would be better to remove portions of the ribs or to let the patient go on to death. Certainly medical treatment was of very little help in these cases. This child was fed Walker-Gordon milk, kept out of doors on a balcony, and everything was done in the way of hygienic treatment without success, so that if surgery had anything to offer it was worth while giving it a trial, as had been advocated for tuberculosis of the lungs and also for bronchiectasis.

The Methods Used in Conducting a Class for Undernourished Children.—Dr. CHARLES HENDEE SMITH gave a talk on this subject which he illustrated with lantern slides. He stated that at least 10 per cent. of the children in the schools of New York City were undernourished; in some schools the percentage rose to 30 per cent., It therefore behooved us to do something. The formation of nutrition classes was one of the means adopted to meet this problem. The nutrition class at Bellevue was started on November 1, 1916. The class or group method, was the only means by which large numbers of children could be treated by a single physician. The class for undernourished children suggested nothing new so far as the principle was concerned. The methods that had been applied to the nutrition classes had been worked out in the tuberculosis and other classes at the Vanderbilt Clinic at St. Luke's Hospital and elsewhere. The class methods had been employed by Dr. William Emerson of Boston, and much credit was due him for having called attention to this important subject. The undernourished children coming under his care had come from the hospitals or the general clinic. A large part had come from school nurses. Every child five pounds or more under weight for his age had been accepted. There had been 250 or 275 children in the classes, and in addition a large number of other children had been examined who had been eligible for various reasons. Of these 180 remained as active members of the class. The parent or some adult member of the family was required to attend the class and to receive instruction, at the first few visits at least. This, however, was not a hard and fast rule, and no child was debarred because a parent could not accompany him to the class. When a child entered the class his general history was recorded, including the diet he had been receiving, the time he slept, the length of time spent out-of-doors, etc. A complete physical examination was made. A social worker got the social and economic facts having a bearing on the case and that might have a direct relation to the condition of malnutrition in the child. A printed slip giving instructions in hygiene and a diet list were given the mother. In their first diet lists some of the more expensive articles of food occupied too prominent a position; these had been changed and in their stead were placed cheaper articles having an equal nutritional value. They had a food exhibit of artificial foods showing the day's ration arranged in the form of three meals. By quickly changing the plates they showed how one article might be substituted for another of equal caloric value. This graphic demonstration served to impress the facts on the mother's mind. It also served to emphasize the importance of properly selected, well cooked and well served food. Nearly all of the portions represented 100 calories of the various articles of food, but they did not say much about calories in attempting to teach these ignorant people, as they had found it better to show them definite meals arranged in amounts proper for a child. With more intelligent classes of people it was perfectly easy to give the teaching on the basis of the caloric value of foods. Dr. Smith said they gave their class instruction by means of class talks to the mothers, by using wall charts, and showing them what made a child gain in weight and what made him lose. They had a weight chart for every individual child and a collective weight chart showing the weight curves of every child in the class. There were also sheets for home records, and each child was supposed to keep this record showing just what he had eaten, how many hours he had slept, how much time he had spent out-of-doors and exercising, when his bowels had moved, etc. They used for this the sheet they had found successful in their cardiac cases. At first the child returned each week to be weighed and examined; later he came only once in two weeks if he was progressing favorably. The interval between visits was gradually lengthened as the child approached a normal weight for his age. By this class method the child had his attention directed to the faults of others and profited by them, and a spirit of competition was aroused which could be used with advantage. They had found it a help to offer prizes and to stick green and gilt stars on the weight charts in order to stimulate competition. The question might be asked whether this method had been found worth while and

what were the results. They were all agreed that the past winter had been a most unfavorable time for conducting such an experiment on account of the high cost of living. They had had to equip and organize the clinic and also to devise methods as they had gone along. Of 51 boys and 50 girls who had been under observation over six months the average of the entire class was 1.4, the expected gain. Sixty-three had done better than the average, having gained 1.7 times the expected gain; 24 had gained at the average rate; 23 had gained less than the average. The best record was five times the expected gain. The causes of malnutrition in these children might be divided into organic and hygienic. Of the former, latent or chronic absorption from diseased tonsils or bad teeth, obstructed nasal breathing, and various other maladies were the cause. Of the hygienic causes the chief was insufficient and improper food, insufficient exercise, air and sleep, uncleanliness, and economic reasons. For this whole group of children the average family income was $12.40 per month per person. The 63 children who did well were from families in which the weekly income was less than $12.00. In a number of instances it was found that the children coming from families whose incomes were less than $12.00 per week did better than those coming from families in which the income was more than $12.00 a week, so that the malnutrition in these children seemed to be not so much a matter of income as of lack of knowledge as to what constituted a suitable diet. Of the 23 children who did least well, however, 17 had an income of about $8.00 per month per person in the family. Dr. Smith said that when he came to judge of malnutrition he found that we had no standard that served as a guide. In using the Dunfermline scale a great deal depended upon the personal equation of the examiner. Basing a judgment on a comparison of weight to height was very misleading and gave no guide as to the degree of malnutrition if a child was under height for his age. A child might be both under weight and under height and at the same time he might have the correct weight for his height, and yet be underweight for his age and really undernourished. The younger children did not do as well as the older ones in making up weight.

The Chlorotic Type of Anemia in Infants and Children.—Dr. HERMAN SCHWARZ presented this paper, the purpose of which was to show that a type of anemia existed in infants and occasionally in older children in which the blood picture corresponded to that of chlorosis in adults, and that this form of anemia responded marvelously to the administration of iron. Only those forms of infantile anemia were considered which produced a blood picture similar to that in adults. The work of Bung and his associates, especially Abderhalden, had shown that a diet containing very little iron could produce in young animals a blood very similar to that of chlorosis; in older animals and adults, under similar conditions, this form of anemia was not produced. The clinical features of this form of anemia in infants and children were not necessarily distinctive; it required a blood count and a hemoglobin determination in order to discover its presence. Iron medication frequently produced the same brilliant results as it did in the chlorosis of adults. It was surprising how little this simple or perhaps essential anemia was described in our text books on children considering the frequency with which it was found. In order to illustrate this frequency it was only necessary to state that within a few months the writer had been able to collect 40 cases. Of these 40 cases 14 were discovered earlier than three months, 29 were seen before the first year, and three as late as the eighth year. Of the 29 cases occurring under one year, there was no doubt in his mind that the condition existed a longer or shorter time before it was discovered. Very often the appearance of the child does not lead one to suspect its presence. In 18 of the 40 cases blood examinations were not made until the children had been under observation weeks or months. Most probably these cases began in early infancy and did not become apparent until the children were between twelve and sixteen months old. In 23 of the cases the pallor was first noticed between the first and second years. From an analysis of this series of cases it soon became apparent that this form of anemia occurred in premature children, in twins, and in those who had a rather stormy feeding history during the first three months of life. In cases with such a history, although without any appearance of pallor, examination of the blood often showed this type of anemia. Of 28 cases in which a history of the feeding for the first three months was obtained 14 had the breast alone, 10 had the breast and bottle, and four had the bottle alone. The feeding in the older children was in most of the cases a very rational one, being fairly mixed, although in a few cases the condition seemed to be definitely in connection with the feeding. In their series of cases, 28 were boys and 12 girls. This was the reverse of that found by Monat and did not coincide with the chlorosis of adults which almost never occurred in the male. Constipation was not a factor. At times there was a family history of chlorosis or other forms of anemia, although this was not usually the case. There were no special symptoms, though at times there was loss of appetite or capricious appetite; rarely constipation. Intestinal derangement was not a common feature. Clinical examination showed that these children presented one of two types. They were either premature, congenitally weak and usually underweight, or they had a good panniculus adiposis and were well fed and happy. Pallor was in some cases marked, in others hardly discernible. Apart from the general types nothing was characteristic. Systolic murmurs were present in only three of the entire series. The spleen was rarely felt. Examination of the blood in these cases, as seen in the tables, showed that the hemoglobin greatly diminished but the red blood cell count rarely fell below three million and was frequently between four and five million. There was a great disproportion between the number of red blood cells and the hemoglobin. The index was always less than one, and usually between 0.4 and 0.6. The leucocyte count ranged between six and ten thousand, with a differential count presenting no deviation from the normal. A tendency to lymphocytosis is noted at times but this is difficult to judge accurately on account of the tender age of some of the children. The red cells occasionally show poikilocytosis and anisocytosis. Nucleated red cells were rarely found. Blood platelets range between two hundred and three hundred thousand. The blood volume was normal in five cases estimated by means of Epstein's method. A review of the literature on this subject showed that the iron balance had something to do with the hemoglobin without doubt, but just how much was unknown. The etiology of this type of anemia in infants was still obscure. A perusal of the histories showed that the prematures, the congenitally weak, twins, those born with low birth weights and those having difficulty with nursing hygiene during the first few months, had a predisposition for this form of anemia and developed it with great regularity. The author had been able to prevent this anemia in prematures and twins by the regular and early administration of iron and cod liver oil. Constitutional dyscrasias, such as the exudative diathesis, neuropathic tendencies, etc., seem to play but a small part in this type of anemia. Gastro-intestinal conditions and dietetic errors might be factors, as seen in two of these cases, but when one observed the good general condition one was forced to acknowledge that there was some other factor present in addition to the diet. In the treatment of these cases large doses of iron seem necessary, and it had been his custom to give no less than ten grains of saccharated carbonate of iron, three times a day, to a very young infant; fifteen grains, three times a day, in the second year, and later, usually five grains of the unsaccharated carbonate of iron, three times a day. Once the hemoglobin reached the normal the iron might safely be stopped, and the anemia usually did not recur unless extraneous infections, grippe, etc., occurred, which often caused a relapse. In some instances he had only given iron without any change in diet, and had had the same good results. On the other hand, the changing of the diet without iron had frequently failed to increase the hemoglobin.

Blood Transfusion (Citrate Method) in Hemophilia Neonatorum.—Dr. RICHARD LEWISOHN read this paper, which was accompanied by a cinematographic demonstration. He said that one of the most gratifying fields for the use of blood transfusion was in the treatment of bleeding in new-born infants, so-called hemophilia

neonatorum. This name was not a very appropriate one because these infants were not hemophiliacs in the true sense of the word. True hemophilia usually occurred as a family disease and was never permanently cured by blood transfusion. On the other hand, the abnormality of the composition of the blood, which caused bleeding in the new-born, was absolutely cured by a single transfusion; and these individuals grew up as perfectly normal individuals, not showing any tendency to bleeding in later life. The real cause for bleeding in these new-born infants was not really known. It might be assumed from a theoretical point of view that among different bloods available (father, mother and other relatives, professional donors) the mother's blood would be absolutely contraindicated for the cure of the disease. The whole intrauterine existence of the fetus was based on the mother's blood. In might seem a very logical conclusion to use any other blood in preference to that of the mother. Such an assumption, however, was not warranted by the facts. It had been proven without doubt in a great many cases that the mother's blood was just as efficient as that of any other donor. Evidently some substance of the mother's blood, as calcium, prothrombin, thrombokinase, was not transmitted to the placenta. The mother should be used as the donor in every case of this type for the following reason: Cherry and Langrock had shown that the mother's blood could be used safely without hemolytic tests for the new-born infant whereas the blood of the father and other blood relatives required a careful test to prevent hemolysis and agglutination. This observation was of the greatest practical importance because it was almost impossible to obtain sufficient blood from the baby for the necessary tests. Furthermore, these cases were extremely urgent, and with the mother always available valuable time was saved. Dr. Lewisohn said his personal experience comprised eight cases, six of which were permanently cured by a single transfusion. The method employed was the citrate method previously described in a series of papers. The mixture of the blood with a minute amount of sodium citrate (0.2 per cent.) prevented coagulation of the blood during the transfer from donor to recipient. The use of the citrate method in children was followed by no reaction or chill in any of the cases in this group. The citrate method was far superior to any other method of blood transfusion in the treatment of hemophilia neonatorum on account of its flexibility. These infants were usually brought to the hospital on the second day after birth. A member of the house staff was sent to the patient's home and returned with 100 c.c. of citrated blood taken from the mother. A superficial arm vein in the elbow region of the baby was then exposed by a very small incision. The blood heated to body temperature by immersion in warm water was introduced through a fine cannula. In using this method it was unnecessary to expose the external jugular vein or to introduce a cannula into the longitudinal sinus. The writer's records showed that in a number of cases transfusion stopped the bleeding immediately and permanently in cases in which the previous injection of serum had not effected any diminution of the bleeding. Serum and intramuscular injections of blood might be tried, as they seemed to stop the hemorrhage in a certain number of cases, but if the bleeding recurred blood transfusion should be immediately resorted to.

Dr. Oscar M. Schloss asked Dr. Schwarz by what method the hemoglobin was determined and what he took as the normal standard. For a color index to be of real significance these facts must be known. The hemoglobinometers in ordinary clinical use were not of great accuracy, and at present the method of Palmer or that of Van Slyke were the ones of choice. The instruments in ordinary use were calibrated for adults and the percentage readings would not give an accurate color index for children as the hemoglobin of children was much lower than that of adults. Williamson, using the spectrophotometer, found that at certain ages the normal hemoglobin content varied from 14 to 10.5 grams per 100 c.c. of blood. With such a wide variation in normal infants it was difficult to determine the color index accurately even with the use of a satisfactory method of determination. Dr. Schloss recalled that a few years ago he advocated the use of intramuscular injections of whole blood in the treatment of hemorrhage in the new-born. He believed that in the milder cases this method was of value. At that time direct transfusions only were used, and only two cases had been reported in which transfusion was done in new-born infants. The simple technic or citrate transfusion as developed by Dr. Lewisohn was, in his opinion, the method of choice in all the severer cases.

Dr. Edward D. Peterson stated that his experience had been with unmodified blood, but since he had seen Dr. Lewisohn's method he had used the citrated method largely in adults, but he had not had a case of hemophilia neonatorum on which to try the citrated method. He did not believe there was a great deal of choice between the methods. Dr. Peterson said he believed we could divide these cases into two groups, the purpuras and the true hemophilias, and in either of these blood therapy was effective. The whole blood was a simple way of meeting the condition, and if that failed then transfusion might be done. Dr. Peterson said that in his opinion the whole blood was better than the serum.

Dr. J. Finley Bell said that he had had the opportunity of testing the various salts of iron. He had a case of chylous ascites and made observations as to the excretion of iron through the abdominal lymphatics; the iron reached the blood through that channel. Ovo-ferrin and other preparations of iron were administered and then an examination of the chylous fluid made a week later. After the administration of the ovo-ferrin and other preparations there was no increase in the iron content of the chyle, but after the administration of the ferric salts there was an increase in the iron content. The old doctors who administered the acid salts of iron were doing the right thing, though they were not able to give a scientific reason for it.

Dr. May G. Wilson reported that the results that they had obtained in their nutrition work at Cornell had been somewhat similar to those described by Dr. Smith. Even if one got a gain of only 1.7 per cent. above the expected gain, that was no reason for feeling discouraged. The improved nutrition of these children might be seen not only by their gain in weight but by the fact that they were doing their school work better and were eating and sleeping better. The work had brought out evidence that the children were improved in many ways.

Dr. John L. Kantor described the work being done by the Bowling Green Association, in which he had been particularly interested. This locality afforded certain unusual conditions; it was shut off from the rest of the city by the financial district, the houses were very old and the sanitary conditions bad, so that one found here probably the worst slums in the city. The population was composed mostly of Syrians, some Slavs, Italians, and Irish. They had in connection with the neighborhood work a medical center which was established in response to the need for such a center, which was demonstrated as a result of school inspection. They had used this agency as a sort of clearing house for children and had tried to coordinate a number of agencies. The work of this center was not merely medical but it was social and economic. Their work had in one respect been a little more encouraging than the work cited by Dr. Smith in that most of the children had gained rather than lost as the result of vacations. They had co-operated with a home in the country where cardiac cases were taken. The question of classification was very important, and one was rather surprised that Dr. Emerson should have selected the normal weight for height instead of for age as a standard. The latter method was not so complicated as one might suppose from the diagram shown by Dr. Smith, as they did not handle the overweight cases. They only dealt with the slim and underweight children. The parents in their neighborhood were of little help to them as they did not understand the English language and hence most of the work had to be done with the children alone. Of the children coming under their care about 78 per cent. had gained 1.6 times their expected weight. By the Dunfermline scale classes One and Two were ruled out, and they only dealt with classes Three and Four. Those belonging to class Three were better than 15 per cent. under-

weight and all the fourth class were worse than 15 per cent. underweight. There was another point which deserved attention and that was that if a child got a little money he immediately converted it into candy. It was difficult to see how much could be done to improve the nutrition of these children unless one could prevent the candy habit. We might do quite as much good by abolishing the candy shops as by abolishing saloons where alcoholic beverages were sold.

Dr. JOSEPH LOSEE stated that he had seen many of the type of cases which Dr. Lewisohn discussed at the New York Lying-In Hospital, where Dr. John E. Welch first made use of the human serum treatment for this type of case. They were still using the serum at the hospital and had very good results, but occasionally the bleeding was not checked by very large amounts of serum, and transfusion would be more beneficial both as a therapeutic agent and to supply the volume lost. The best classification of the hemorrhagic diseases had been made by Hurwitz of the University of California. He suggested that in hemophilia and the hemorrhages of the new-born there was an absence or marked deficiency in the prothrombin in the blood. He advised transfusion of blood as the radical therapeutic agent. He also recommended the use of whole blood and fresh blood serum subcutaneously. He stated that the old serum was practically of no account, for the thrombin which was present in the fresh serum had been converted into metathrombin, which had the opposite effect to that which was desired. He had endeavored to transfuse these infants by exposing the superficial veins in both the arm and the leg. but had been unsuccessful and came here this evening to witness its demonstration, but was much disappointed to find that Dr. Lewisohn had demonstrated his method of transfusion on the adult and not on the new-born. For the past two years the superior longitudinal sinus had been the route used by some for intravenous medication. This seemed to be rather a courageous step on the part of the operator, and the speaker had confined his attempts to the cadaver. Here he found it very simple to perforate the wall of the sinus, even at the posterior angle of the anterior fontanelle where it was the deepest. At the hospital they had been using the Lindeman method for transfusions in the adult with good results, but in the new-born, on account of the small size of the veins, it would be necessary to inject the blood more slowly than in the adult, and he felt sure that the citrated blood could be more easily handled. Dr. Losee asked Dr. Lewisohn to demonstrate the cannula which he used in the veins of the new-born, for he was not yet convinced that it was an easy procedure.

Dr. SCHWARZ, in closing his part of the discussion, said he realized how difficult it was to classify children from the nutritional standpoint. When he read that 40 per cent. of the children in New York were undernourished he had his doubts. We must learn to differentiate between undernutrition, malnutrition, and deficient nutrition. This subject should be studied more thoroughly, and physicians should get more definite ideas with reference to it before bringing it before the public. In reply to Dr. Schloss' question, Dr. Schwarz said they had used the method of Kütner for the determination of the hemoglobin. The work of Bunge left no doubt that there was less hemoglobin in the blood of premature babies and twins. The question of the lactation period had a great deal to do with anemia. Animals with a long lactation period had a large amount of reserve iron in the liver.

Their observation was that woman's milk contained more iron than cow's milk. The large deposit of iron in the liver was necessary to tide the child over the period during which he was dependent upon milk for his nourishment. The whole question was very puzzling.

Dr. CHARLES HENDEE SMITH said he was very sceptical about the Dunfermline scale at first and was quite surprised in charting weights to find that the undernourished children fell quite readily into two groups. There was a distinct group just a little underweight, about five or ten pounds, and another group ten or fifteen or twenty pounds underweight. After considering the whole problem it seemed that the best way of dealing with it was to have these nutrition classes. We had had the problem of infant mortality in the past and the milk stations and feeding classes had helped to solve that. Now we had the nutrition problem, and the nutrition classes were the best means of attacking it. A nutrition class should be started in connection with every hospital and dispensary and perhaps in every public school.

Dr. LEWISOHN said the only reason he did not use the longitudinal sinus was because it was so easy to use the arm vein. He had been surprised to find how large these arm veins were in infants. With a little compression by the hand one could find the vein easily and introduce a fine cannula without any difficulty.

Stated Meeting Held December 12, 1918.

Dr. HERBERT B. WILCOX IN THE CHAIR.

Intestinal Disturbances in Children Depending on Mechanical Agencies. Lantern Demonstration.—Dr. CHARLES GILMORE KERLEY made this presentation. He said that the most difficult cases that came to him—those presenting the hardest problems for solution—were cases of persistent gastrointestinal derangement in the child after the period of infancy up to adolescence. The usual procedures of examination of gastric contents, stools, and the urine failed in many instances to supply the information which was necessary for a successful management of the patient. With the idea of shedding additional light on difficult diagnostic and therapeutic problems, he began several years ago to make *x*-ray studies of all cases that promised to be or were difficult. In a series of fifty-seven cases, ranging in age from eighteen months to two years, he had had the benefit of an *x*-ray examination. With three exceptions, all these examinations were made by Dr. Le Wald at St. Luke's Hospital. The conditions found in the stomach series were dilatation, ptosis, pyloric spasm, pyloric obstruction (organic), and hypertonicity. Types of all these were shown in the slides. In the study of the stomach and small intestine a mixture of bismuth, one part, to eight parts of farina or cream of wheat gruel was fed to the child, and the radiogram taken at intervals subsequently. For the study of the large intestine a barium mixture was introduced into the lower bowel and after reverse peristalsis had carried the medium through the large intestine to the cecum, the radiogram was taken. The symptomatology of the stomach cases consisted in stomach pain (moderate or extreme colic), vomiting at intervals, rumination, cribbing, accumulation of gas (moderate or excessive), habitual loss of appetite, convulsions, chronic urticaria, secondary anemia, and failure to grow. The intestinal abnormalities included the following: Dilatation of the colon, localized sacculations of the colon, ptosis of the colon, adhesions of the colon, sacculations of the cecum, sacculations of the sigmoid, dilatation of the sigmoid, dilatation of the rectum, rectal prolapse, and abdominal tuberculosis. The intestinal symptomatology included abdominal distension, chronic constipation, chronic diarrhea, intestinal colic, interval vomiting, persistent slight elevation of temperature, secondary anemia, developmental defects (physical), and mental irritability. With dilatation and sacculations of the sigmoid one was very apt to find derangements of peristalsis in the stomach which sometimes amounted to dystalsis; the peristalsis did not begin at the cardic end of the stomach and proceed rhythmically, and there resulted a pylorospasm.

Dr. MAX EINHORN said that although he had not had much experience in the diseases of children, he treated them occasionally, and he felt that these conditions as seen in children were similar to the conditions seen in older people. Abnormalities in the position of the stomach and intestines were apt to cause various troubles not always of the same nature in older people. In enteroptosis there might be prolapse of the colon, stomach, kidneys, etc., that did not present any symptoms at all, but the majority of these people showed some diseased conditions. Many were very thin; many were constipated, and some had membranous colitis. That showed that the position and mechanical disturbance of the intestinal organs was apt to produce symptoms but not necessarily the

same in each case. Some would show dilatation of the stomach and still have good motor function, the organ being empty in the morning, when fasting, and perhaps one would find an abnormality if the *x*-ray were taken. But if there was a considerable retention of food present, one would almost always find severe symptoms. In diagnosing these conditions one took into consideration not only the position and size of the stomach, but also the motor function. Whenever the stomach did not empty there was a severe condition behind it. In speaking of diagnosis, Dr. Einhorn said that the *x*-ray helped a great deal as it showed delay and retention; delay was also shown in the bowels, but in many instances this might be found without the *x*-ray, if one washed out the stomach five or six hours after a meal. In grown people it was of the greatest importance to ascertain the condition of the fasting stomach, that was in the morning before breakfast. If the stomach was found to be empty at that time these patients got along very well with appropriate diet and care, but if the stomach did not empty by morning the food decomposed and that meant very severe trouble. How this was in infancy he could not say, but he thought the main point was whether the stomach was empty in the morning, at least in the older children.

Congenital Hypertrophic Stenosis. A Manifestation of the Hypertonic Infant.—Dr. SIDNEY V. HAAS read this paper in which he reviewed a recent communication in which he had described under the title of the "Hypertonic Infant," a syndrome made up of hypertonicity of the skeletal muscles and a tendency to spasm of the unstriated muscular system accompanied by psychic and physical irritation. The cardinal symptoms of this condition were vomiting, often projectile in type, crying, insomnia, constipation, underweight, occasional cyanotic cold extremities and subnormal temperature. These symptoms were relieved by atropine. The conclusion that the etiological factor was a disturbance of the vegetative nervous system seemed justified. Included among these cases were a number of straightforward cases of pylorospasm, in two of which operation had been advised. All, without exception, cleared up under the use of atropine. Up to the time of the publication of the above paper and since, no case with a complete and absolute stenosis of the pylorus had come under the writer's notice, until the case which he now described. This baby was first seen on April 25, 1918, when five days old. The labor was normal, there was no asphyxia, and the child weighed eight and one-half pounds. Physical examination was negative except for vomiting, which occurred before the child was put to the breast. All the usual attempts had been made to improve the child's condition without avail. The infant cried constantly and was emaciating rapidly. There had been no food stools, no gas had passed per rectum, and there had been no urination. The abdomen showed distinct peristaltic waves, and in the region of the pylorus a small mass could be felt. The stools were greenish black mucus containing bile, their character not having changed since the meconium was expelled. The diagnosis of hypertrophic pyloric stenosis was undoubted with the single reservation of the remote possibility of a congenital atresia of the duodenum. The treatment instituted was feeding five minutes every two and one-half hours preceded by the administration of one drop of a 1/1000 solution of atropine sulphate in one dram of water, to be increased daily by one drop at each feeding until the physiological effects were observed. The first dose was administered at 4 P.M. The 6 o'clock feeding was retained better than any previous feeding, and the crying, which had been constant, was diminished; during the next forty-eight hours projectile vomiting occurred only three or four times in twenty-four hours. Forty-two hours after the atropine was begun the first trace of milk stool was noticed. From this time the child made a gradual recovery. The weight on April 28 was six pounds twelve ounces and on Aug. 1 it was eleven pounds three ounces. Three weeks previous to this date the atropine had been discontinued. The maximum amount of atropine administered was six drops seven times daily. Dr. Haas reviewed a case of hypertrophic pyloric stenosis reported by B. K. Rachford in which the onset occurred when the child was three weeks old. At the age of ten weeks the child was operated on by the Rammstedt method, after which it made an excellent recovery. At operation a tumor 2 cm. long by 1 cm. thick and of cartilaginous hardness was found. At the age of seven months the child died. The autopsy report stated that this child undoubtedly died as the result of an unusually enlarged thymus (65 grams). Upon examination the pyloric orifice was found normally dilated and the pyloric mass which was distinctly seen at the previous operation had disappeared. From this case the writers concluded that if the pyloric sphincter was so cut as to leave the pyloric orifice patulous and prevent muscular spasm of these fibers, the pyloric tumor disappeared entirely and this within a few months. Sudden death in these cases was due to enlarged thymus. Sudden death followed successful operations and sometimes occurred during medical treatment.

Dr. MAX EINHORN related that ten years ago, when he began to enter the duodenum with the duodenal bucket and thread, he had an idea that it might be possible by this means to stretch the pylorus. At that time he had a case of persistent vomiting in a child six months old, and after careful examination found that there was retention six hours after the ingestion of food. He tried to see if he could enter the duodenum by giving the child a small olive with the thread. The introduction of the olive in children was very easy; it might be given with the breast or milk bottle, but one must know the length of the thread from the lips to the duodenum, and one must be sure that the thread was long enough to reach to the duodenum. The olive was left in for six hours and then pulled out, and if one found bile on it he knew that it had been in the duodenum. Following this procedure, and using olives of different sizes, one could learn the degree of patency of the pylorus; if the olive had passed into the duodenum there would be a little resistance when it was withdrawn, but if it was only in the stomach it came out easily and there was no bile on it. Dr. Einhorn recalled one case in a little boy three or four weeks old in whom the pylorus was stretched in this way, who was now grown and had had no further trouble, and he had had several quite similar cases. He also recalled two instances in which the children were too far gone at the time of the stretching and both died. He said he only mentioned these cases to show how near death these patients often were when one was called in to do something. He felt quite sure that if stretching the pylorus were tried by pediatrists they would find that in some instances they would meet with great success. Whether he was dealing with a pylorospasm or a stenosis in these cases it was difficult to say, but stretching was useful in benign strictures in grown persons. This procedure did not harm, and if it was not successful the child could be turned over to the surgeon. He was of the opinion, however, that the child should first be given the benefit of reaching the duodenum and trying to widen the pylorus in this way. He did not think atropine relaxed the spasm in each case, though it might do some good. He thought a warning should be sounded against the use of atropine for a long time, for he had seen symptoms due to the prolonged use of this drug. If there was too much acidity the patient might not improve. He recalled a case of spasm of the pylorus that did not respond to atropine. This patient was cured by stretching. He was sure conditions were found in infants and children similar to those encountered in older people.

Dr. JOHN DOUGLAS stated that ten or twelve years ago he had heard a discussion as to the relative value of medical and surgical treatment of hypertrophic pyloric stenosis and even at that time the history of a considerable number of cases treated by surgical means compared with cases treated by medical means was decidedly in favor of those treated surgically, and that was by the old method of gastroenterostomy. He felt sure that the majority of pediatrists would agree that by means of the Rammstedt operation this mortality had been very much lessened, and that this procedure was much to be preferred, because in treating a child with atropine there was danger of carrying it along until it had reached such a stage that it could

not be helped by surgery. The mortality in these cases with the Rammstedt operation was very small if operation was performed early. It might be that some cases were entirely due to spasm and that these would be helped by atropine, but anyone who had cut through the thick gristle and knew how careful one must be not to cut entirely through the mucous membrane had observed that there was a distinct difference in the thickness and in the actual amount of tissue and that no amount of simple contraction could make the wall so absolutely thick and hard. Dr. Douglas then referred to another point, namely, that a considerable number of cases of moderate true hypertrophy of the pylorus also had spasm and this permitted a little of the stomach contents to pass through at times. When there was a spasm on top of the hypertrophy, the spasm might be relieved by atropine, and if the hypertrophy was not too great the stomach contents might pass through. It seemed to him, however, that to advocate the treatment of true hypertrophy by atropine was very dangerous teaching. He could not help but feel that the Rammstedt operation was less dangerous than one-twenty-fourth of a grain of atropine daily in an infant a few weeks old.

Dr. L. E. LaFetra expressed himself as in hearty accord for the most part with the remarks Dr. Douglas had just made. If we thought carefully over our cases we must recognize that even when hypertrophy was present there was nearly always more or less spasm which frequently was sufficient to complete the stenosis. In those cases that were relieved by atropine, the spasm, whether the whole or only the partial cause of the stenosis, was relieved sufficiently to allow food to pass through to the duodenum. In reference to Dr. Douglas' adverse comment on the probable delay caused by the use of atropine, he would say that the modern pediatrist was well aware that the operation to be successful must be performed before the baby had lost its vitality. Only two or three days were necessary for a satisfactory test of the atropine treatment. It must be emphasized once more that the presence of a peristaltic wave or a hard stool did not necessarily indicate either hypertrophy or operation. It was the function of the pylorus that was important, and this must be judged by the amount of stomach residue, the character of the stools, the weight of the baby, and its general condition. In closing, Dr. LaFetra thanked Dr. Haas for having pursued the topic of atropine treatment and for having brought it to the attention of the profession. It was a most important method and would relieve those cases in which spasm was the chief factor in the condition. With regard to the case reported by Dr. Haas, he regretted, however, that he should have to disagree with his diagnosis; the baby was probably suffering from pylorospasm.

Dr. Charles Gilmore Kerley stated that he had used atropine with very satisfactory results in a good many cases. He hoped to report this at a later date. In only one case had the dosage of one drop of the 1/1000 mixture caused trouble. In this instance he was obliged to reduce the dose to one-half drop. He did not believe, however, that atropine could have any effect whatever on a case of true hypertrophic stenosis. From his experience he would not have the courage after a child had lost a couple of pounds to delay operation, for the reason that the longer operation was postponed in these cases the greater was the danger to the child. He still believed that early operation was the only means of saving these cases; by early operation he meant before the case had become a grave surgical risk. In a series of cases reported before the American Pediatric Society last May he had a mortality of 15 per cent. In three of the fatal cases he was convinced that death would not have occurred if surgical intervention had not been deferred until too late, and that was the risk incurred when these cases were treated too long by medical means.

Dr. Haas, in closing, said that personally he had seen the good results of dilatation in these cases carried out by Dr. Einhorn's method or by the duodenal catheter. This would seem to afford additional evidence that agencies other than operation might accomplish a cure. As to the fears Dr. Einhorn expressed regarding the prolonged use of atropine, he might say that he had been using atropine for three years and used it for eight or nine months continuously without bad results. One baby had been receiving four drops in five feedings over a considerable period of time, and another child from time to time must have atropine to allay irritability and had taken it over long periods. He had repeatedly given atropine for months without any apparent ill effects. Dr. Douglas was quite right in saying that anyone who had seen the condition present in hypertrophic stenosis ought to apply for surgical aid. This was his belief before he knew as much about atropine as he did to-day. He had tried atropine in many cases of pylorospasm and always with complete relief of the symptoms. The largest dose of atropine given was one-sixteenth of a grain in twenty-four hours. Dr. LaFetra had disagreed with the diagnosis of the case and Dr. Kerley said he could not understand the disappearance of the tumor. A review of Dr. Rachford's case cited in the paper would explain this point. Regarding the dosage of atropine, if there was flushing that need give no concern; it was when the child grew pale that there was danger. Fever and flushing disappeared promptly when atropine was discontinued. It took one hundred years to discover the proper use of digitalis, and it might take another one hundred years before we learned to use atropine properly. There was no benefit to be derived from atropine until an adequate dose was reached. As a rule, two drops at a feeding did not effect a clearing up of the symptoms. Dr. Kerley spoke of a child that could not stand one drop at a feeding; this did occur but as a rule children in which this condition was present stood large doses of atropine well. Dr. Haas said that while he would not detract in any way from the surgical work which had been carried on so brilliantly in this line, he wished to call attention to the fact that it did not take a week to find out whether the child was improving under the use of atropine. One could usually find out within forty-eight hours by the use of atropine whether the case was a surgical one or not.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Nerve Control and How to Gain It, by H. Addington Bruce. 303 pages. Price, $1.00. Published by Funk & Wagnalls Company, New York and London.

Autotherapy, by Charles H. Duncan, M.D. 349 pages. Illustrated. Price, $5.00. Published by Dr. Charles H. Duncan, 2612 Broadway, New York.

Massage and the Swedish Movements, by Kurre W. Ostrom. 188 pages. Illustrated. Price, $1.00. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

Genito-Urinary Diseases and Syphilis, by Charles S. Hirch, M.D. 334 pages. Illustrated. Price, $1.50. Published by P. Blakiston's Son & Co.

Paper Work of the Medical Department of the U. S. Army, by Ralph W. Webster. 531 pages. Illustrated. Price, $5.00. Published by P. Blakiston's Son & Co., Philadelphia.

Transactions of the American Otological Society. 612 pages. Illustrated. Published by the Society.

Report of the Surgeon General of U. S. Army. 722 pages. Published by Government Printing Office, Washington.

A Compend of Pharmacy, by F. E. Stewart, M.D., Ph.G., Phar.D. 185 pages. Price, $1.50. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

Dietetics for Nurses, by Fairfax T. Proudfit. 429 pages. Price, $2.25. Published by The Macmillan Company, New York.

Annual Report of the Surgeon General of the Public Health Service of the United States. 373 pages. Published by the Government Printing Office, Washington.

Miscellany.

Petrograd Under the Bolsheviki.—in the *Presse Médicale* for November 11, Marcou writes at length on this subject. The author is the executive of the French Hospital of that city and has practised there for 17 years. The war was never popular there, and the revolution of March, 1917, he says, was purely for the purpose of bringing it to a close. The soldiers and workers were veritable mutineers against warfare. The results were anarchy and desertion at the front, anarchy and sabotage in the shops, and *jacquerie* in the country. Theorists and philosophers certainly had no part in this revolution. The soldiers did not propose to be killed longer for a cause they did not understand, while the artisans wished the highest pay for the shortest hours. The peasantry went into the movement for land and pillage. The author does not regard the Russian mob as different from the mobs of other countries, but the inhibitions are weaker. The well-known physiologist Pavloff took this view in stating that there was lack of equilibrium between dynamics and inhibition among his compatriots. The revolution began at Petrograd and spread over Russia; but one thing miscalculated, for after this movement was under way no one worked at all.

Socialism is said to imply organization of industry and proper distribution of wealth, but since March, 1917, industrial Russia had ceased to produce wealth and peasants did not even sow their fields. The town stopped making tools for the peasant and the latter ceased to produce food. The Bolsheviki wished to monopolize foodstuffs, but the rurals would not furnish the latter. Instead they sold what they had in small lots to smugglers at exorbitant rates. Red guards about the towns held up all food packages. The dole of food to the townsmen, always at high prices, did not amount to more than 100 calories a day a head. The balance could only be bought as contraband of the smugglers. The latter calling was most hazardous, for after the smuggler had paid the peasant a fancy price the Red guard was apt to seize the food. Bread went up in price 700 per cent., potatoes 300 per cent., etc. Famine was the natural result, and famine not due to crop failure but to causes wholly artificial. Ninety per cent. of all food consumed was smuggled, for despite the hostility of the Bolsheviki they had to allow enough food to make their own tenure safe. People with money did not starve, which shows that smuggling was successful. The Bolsheviki naturally confiscated enough for their own private needs. The medical men, who were given some leeway in regard to their sick patients, abused the privilege at times. Young children suffered greatly but older ones and adolescents much less, the latter being able to utilize food articles of the smoked herring type. Adults up to the age of 40 years were very thin but managed to thrive fairly. Adults over 40, on the other hand, were much worse off, and looked not only emaciated but prematurely aged. Their normal resistance to poisons seemed greatly lowered and the author treated many phases of food intoxication which the more robust and youthful did not develop. The edema of inanition was seen in epidemic incidence and attacked the cardiorenal subject rapidly. The hospitals were crowded with these patients, who chiefly died as cardiac or uremic. Typhus became epidemic and on account of the number of mild and atypical forms was often impossible to recognize. Hence serodiagnosis was resorted to with some success, although the theory underlying it seems defective. Grippe with pneumonic complications prevailed as never before. Dysentery and scorbutus did not develop, an omission difficult to understand. For six months past, Marcou says, the people have not known how they have got along.

The author thought, at the time of his writing, that there were evidences that the false beliefs which made possible this state of affairs were dying out and that common sense would replace them. Food was coming in without smuggling but at prohibitive prices. In the towns, armed workers ordered the peasant to supply food at a maximum price. The latter had reacted by destroying their cereals, preferring this course to accepting questionable money. They had no objection to bartering for tools and commodities. On the whole, the outlook is poor, and the author holds that the menace can end only with the complete suppression of Germany's policy in the East, for this policy not only started the trouble but has maintained it.

Recent Spanish-American Investigations Into Leprosy.—Chabas publishes a long article on this subject in the *Cronica Medico-Quirurgica* for last July. The malady has existed in Spain since the time of Phenician and Greek colonization. The earliest asylum for lepers goes back to 1067 and at one time there were 30 in the Asturias. There was a body of physicians appointed by the Catholic monarchs known as *alealdes de lepra.* The disappearance of lepra as a pandemic naturally did away with these repressive measures, which in more modern times are being revived, presumably because of the discovery of Hansen's bacillus in 1878. At that period Vidal, Catalayud, and especially Castellano, recently deceased at an advanced age, began to labor in this field. The medical geography of Spain as concerns leprosy has been exhaustively studied, in spite of difficulties and opposition. Within the past few years these studies seem to have culminated in a special series of articles. Professor Peyri of Barcelona has been at work for seventeen years on the bacteriology of this affection and has recently published some important conclusions, such as on the variable virulence of bacilli, and the conditions of viability. Other Spanish bacteriologists have also made valuable discoveries in regard to laboratory technique including inoculation of animals. The hematology, especially in regard to the positive Wassermann reactions, has received attention in both Spain and Argentina. Much work has been recently done on the subject of insect transmission, and Hansen's bacilli have been found in bedbugs and house flies, while both the flea and mosquito have been accused of transmission on clinical evidence. Evidences of direct contagion, on the other hand, are not convincing in comparison with the data which point to some sort of mediate contagion. In regard to hereditary transmission leprosy never descends as such, but abortion and bearing of inferior children are commonly observed in leprous women.

MEDICAL *VERSUS* SURGICAL TREATMENT OF CANCER.

BY L. DUNCAN BULKLEY, M.D.,

NEW YORK.

IF the statistics which have been repeatedly presented are correct, and they can be readily proved; if the statements in regard to laboratory researches are authentic, and they can be verified by literature, and if the affirmations of the writer here and elsewhere as to results obtained by medical treatment are credible and believed, serious attention should be paid to "the real cancer problem" as presented in previous publications.* In regard to no other disease have the profession and the laity been so blind as they have been in regard to cancer. But from journalistic literature and personal communications it would seem that the medical portion of the profession is beginning to see matters in their right light, and the day dawns brighter for the elimination of the fearful morbidity and mortality of cancer.

What are we to conclude from our studies on cancer, as represented in previous writings? Is the cancer problem solved completely? By no means. It has only begun to be solved, but there have been indicated the lines along which the best prospects are offered. For it is evident that surgery alone has had its day and has failed. Much more observation and study are needed, both in the laboratory and on patients, but along lines quite different from those heretofore followed. The microscope has revealed about all that is possible in regard to the histological characters of the diseased tissue and the morphological elements of the blood. It is refreshing to observe in the report of the Research Laboratory of the Memorial Hospital, signed by Dr. Ewing, that "The extension of research to clinical questions made possible by the increased endowment has not restricted the laboratory studies, but on the contrary, has greatly added to their number and importance. The main topics being investigated include the influence of diets upon cancer in lower animals, the chemical changes in the blood and in tumor tissue, etc." It would be well if it had been added "also in patients in the earlier and later stages of cancer"—but this will undoubtedly follow and unquestionably will be rich in results.

What are we to think of the facts and figures which have been presented from time to time? Can they be ignored? For they have never been refuted in print or in open discussion, athough abundant opportunity has been offered in many medical societies, and the challenge is still open. With the marvelous diminution in the death rate from tuberculosis under rational treatment, can we refuse to apply the same, properly devised, to cancer, whose mortality has risen so alarmingly under the treatment thus far given to it? Can it be anything but a wilful ignorance to ignore this line of effort?

In preceding writings the medical aspect of cancer has been presented in almost every possible light, repeating necessarily much that has appeared in the two volumes on cancer referred to above. Its connection with diet has been developed statistically, experimentally and clinically. The metabolic changes constantly observed in patients with early and late cancer have been recorded, as also the definite changes in the blood. What is lacking to carry a conviction which shall result in a general change of view, as to its systemic or constitutional character, in place of a purely local nature of the disease? Constant new development of cancerous lesions after surgical removal, metastases, or development of the disease in internal organs, and the later phenomena ending in death, all surely point to something more than a local disease. Malignant primary disease in deep organs, the brain, pancreas, kidney, liver, certainly cannot be accounted for by local injury.

The thesis or theory of a systemic or constitutional origin of malignant as well as non-malignant growths is fully sustained by all that is summed up in the one word nutrition. We know that wrong nutrition accounts for tuberculosis, rickets, obesity and many complaints, and we know that nutrition depends upon the food and drink taken; and we know that nutrition accounts for the marvelous results obtained in tuberculosis, in spite of the continued presence of tubercle bacilli. We know, further, that good or bad nutrition depends also upon the proper or improper action of one or more of the various internal organs, and is also influenced by nervous conditions. What reasonable objection can be raised to the assumption that cancer is also due to errors of nutrition? If the latter is true, it follows naturally that the exactly proper food and drink, together with correct action of all the internal organs, will prevent and cure cancer.

In the first volume above mentioned it was remarked that "The test of everything lies in the results obtained. Theories, discussions, and arguments are all unavailing unless results show their truth." This phrase was repeated with more force in the second volume. It is now four years since those words were first written, and they can now be repeated again with still greater confidence. For these and former years of further observation and

*"Cancer, Its Cause and Treatment." Vols. I and II. Hoeber, New York, 1915, 1917.

treatment of patients with cancer have abundantly demonstrated the correctness of the thoughts presented, while the study of literature has served only to confirm the views which have been held, and on which practice has been based for thirty and more years.

In some few reviews of the previous volumes criticism was made that the diagnosis of the cases reported was made on clinical grounds only, and was not established by the microscope. In answer to this it may be said that in virtually all the cases recorded then or now the diagnosis had been made previously or confirmed by one or more surgeons, who had urged, and in some instances arranged for immediate operation. Also it is well known that biopsy before operation is universally condemned, and it would be particularly dangerous in cases which underwent only medical treatment. Further, it is to be remembered that of the vast number of cases operated on the diagnosis before operation is almost invariably clinical.

Reference and further report may be made concerning some of the cases reported previously as illustrating and impressing what can be done for cancer by non-surgical measures.

In the first volume eight cases of cancer of the breast were reported from among many others, two of whom were followed, remaining perfectly well sixteen years after first beginning treatment. The second two cases had been watched and continued perfectly well for nine years under medical treatment alone; that was four years ago, and traced recently, they remain still well, thirteen years after being first seen. The next three patients had inoperative recurrent cancer, one of whom showed most remarkable gain during her stay of four months and a half in the New York Skin and Cancer Hospital, the details of which were fully reported. One of the cases, in private practice, was watched almost sixteen months, and when lost sight of, that she might take *x*-rays nearer her home in the country, a very large share of the cutaneous nodules had disappeared, she had lived comfortably and without pain, and the disease which would have carried her off long before had certainly in a measure been checked. The last case was described as showing how much could be done even in a most hopeless condition. The lady for two years had neglected a diseased breast, until it was increased to the size of half a large melon, hard and immovable, with some superficial ulceration and with enormous axillary and supraclavicular glands and profound cachexia; the trouble had been revealed to no one until the day before her visit, when a physician and surgeon pronounced it hopeless. For seven months under careful treatment she lived comfortably, the breast softening very greatly, and diminishing to about the size of the other, and the glandular swellings becoming about one-half the size. She passed peacefully away with exhaustion and pulmonary edema, about seven months after being first seen, without having taken a particle of morphine or other hypnotic. In all my cases, even in recurrent cancer, it has so rarely been necessary to use these that I can recall hardly any instance where they were employed; when under full dietetic and medicinal treatment the element of pain is almost negligible. Opiates check the secretions and excretions and retard metabolism, and in my experience increase the tendency to an extension of the carcinosis.

In the second volume nine more cases of malignant neoplasm were reported, in which results of this line of treatment were shown. One was a very remarkable case of sarcoma of the upper jaw, recurrent after operation. The final result of this was a plastic operation to cover the large ulcerative opening which had completely healed in about four months, during which time she had gained from 89½ to 130 pounds, which latter was 10 pounds more than she had ever weighed before. The thick skin graft to cover the opening took at once perfectly, and she remains well two years since I reported the case.

Six cases of cancer of the breast were recorded, three primary and non-operative, and two of recurrent cancer, one of whom had been submitted to four operations, and the last case one with an immense ulcerative mass of the right side of the chest, which was transferred to my medical service in the hospital by the surgeons as being absolutely inoperable. This last patient made a splendid fight for about a year, gaining in flesh, with a blood count raised to 4,110,000, and sleeping well without the opiate she had previously taken. The case was a very difficult one, as the kidneys refused to excrete anywhere near the proper amount of solids required, and she passed away easily a year after entering my service.

Of the other two cases of post-operative cancer of the breast, I may report that the one who had had four operations (Case IV) did remarkably well for a while, although when first seen there was a large ulcerating surface over the site of former operations on the left side, with axillary glands enlarged and a greatly swollen left arm. Five months later she wrote that she felt very well, and "friends think that there cannot be much the matter with me." She made occasional trips from a distant town until about eight months from the first visit, when she fell and broke her hip; treatment was then interfered with for some time, and she began to go down and passed away about a year after I first saw her. The other recurrent case where both breasts had been removed two years previously had a great development of cutaneous nodules on both sides of the chest, forming a veritable "cancer en cuirasse." She was treated in my out-patient cancer clinic of the hospital, and when I presented her at my lecture clinic about four months later her condition was so changed that there was hardly a trace of the nodules on passing the hand over the surface. She had been working hard all the time, and had had no pain since soon after beginning the treatment. She disappeared soon after that and I could not trace her.

Of the three primary cases, non-operative, in private practice, two seem to have recovered, and the other (Case I) made a most wonderful fight under very adverse circumstances, working very hard and with much family sickness and death. She had a hard mass in the left breast, attached to the skin and with enlarged axillary glands, and had been given six months to live by a surgeon of prominence, if not operated on. The improvement in her general condition and the mass in the breast seemed

so good, after the first few months that it seemed as if the disease would yield entirely; she had been to Chicago and back by auto, slept perfectly, had no pain and felt perfectly well. Ten months after her first visit she had a very severe attack of grip, being in bed three weeks in another city, and this with many weeks' neglect of treatment set her back, and she was lost sight of about fourteen months after she had been given six months to live, having taken no opiate.

The other two cases were most satisfactory. One of them, whose breast tumor was diagnosed as cancer by at least four medical men, one of them a prominent surgeon, remained absolutely free from trouble when examined five and a half years after her first call. The other patient (Case II) was reported as perfectly well and free from any breast trouble two years after being first seen, and she had been confined of a healthy child two years ago and was examined on Sept. 23, 1918, more than four years after her first visit; there was no trace of the breast tumor, and she was in excellent health.

Two cases of cancer of the uterus were there reported; both had recovered, as evidenced by the careful examinations of several physicians and surgeons. One of them (Case VII) has been under my constant observation and treatment during these two years, traveling many times from a far-distant city, and is in as perfect health as could be desired, still weighing more than she did at first, walking much, and a recent examination reports that both of these cases are "free from any evidence of disease."

In the second volume was given a list of the cases of malignant disease upon which the studies were based, and it is not necessary to refer to these again, nor to detail others of the cases similar to those already reported. Reference will therefore be made to those seen in the two years since its publication, and only those in private practice will be counted, as hospital cases are not nearly as satisfactory as those among the more educated classes in private practice.

A considerable number of these patients were seen only in consultation or a single time, and a number of them have been treated only for a short period, too short to report definitely concerning them. But there were 21 who were treated sufficiently long to observe distinct improvement, as recorded in their histories. When we recall the ordinary course of cancer, and that when not improving patients constantly get worse, we cannot ignore a steady gain. And in the light of the cases previously mentioned, we must realize that when one improves and goes up hill in regard to the disease and in general health continuously, one is not likely to go down hill at the same time; and moreover, if the same conditions and treatment are faithfully persisted in long enough, there is reason to expect that the final result will be favorable, as it has been in so many instances during the many years past.

During the last two years, since my second volume was published, I find case histories more or less complete of 107 new cases of malignant disease affecting different locations. Of these, 42 cases were of cutaneous epithelioma, which latter are excluded from our present study, as are also a number of cases of suspected cancer and non-malignant tumors. Of the remaining 65 cases there were 39 patients with cancer of the breast, 3 of the uterus, 5 of the stomach, 2 of the rectum, 1 of the bladder, 1 of the kidney, 2 of the prostate, 5 of the buccal cavity, 1 of the axilla and 6 of sarcoma, 3 of which were in the buccal cavity.

These cases were seen in all stages of the disease, 27 were recurrent after from one to three operations and 38 were primary cases. With hardly an exception, I believe all the latter had been seen by other medical men, who had made the clinical diagnosis of cancer, and many had been strenuously urged by surgeons of repute to have an immediate operation as the only hope of saving life. I have elsewhere mentioned the universal belief among the best men that to attempt to take a section for microscopic examination is extremely dangerous in surgical cases, and it would be almost fatal in those treated medically. Many of the recurrent cases have experienced the greatest benefit from the line of treatment advocated in these volumes, as indicated in some of those previously reported and in those to be given. In some instances life has been prolonged far beyond that expected and prognosticated by the surgeon, and with a measure of comfort often most gratifying. As far as I have learned there have been six deaths, but there were probably many more, as a number of those seen in consultation were far advanced. Brief mention may be made of some interesting points in connection with certain primary and secondary cases.

Cancer of the Breast.—The average age of these 39 patients was just 47, the youngest 27 and the oldest 85; twenty of them were between 40 and 50 years of age when first seen. There were 22 married and 17 single. In 24 cases the left breast was affected, in 10 the right breast, both breasts in 3 cases and unrecorded in one case. The duration of the disease before observation varied from a week or two in one instance to six years in one lady aged 59, who had never been operated on; the average was about a year and a half, but there were a number of the primary cases who came quite early, and in them naturally there were the best results. Of these breast cases 19 were recurrent after from one to three operations or *x*-ray or radium, and 20 were primary, who had never been operated on. I must first mention one very interesting case treated in the medical clinic for cancer in the hospital.

Case I.—Mrs. S. J., aged thirty-three, first noticed a lump in the right breast two months previous to her visit, February 28, 1917. This steadily increased until seen, when it was fully an inch and a half in either direction, in about the median line above the nipple, with sharp rather hard edges, and a small palpable gland in the axilla; she had been having sharp pains radiating from the breast to the axilla. To confirm the diagnosis I called in the surgeon in attendance, who at once recognized it as carcinoma and strongly urged an immediate removal as the only hope, my assistants also agreeing as to the diagnosis. She was extremely constipated, the mouth dry, and the saliva acid. She was placed on the usual dietary and medicinal treatment, and in two weeks it was recorded that she felt better than for a year. The lump was materially smaller, though the edges were sharp and nodular. There was no pain, except on extreme exertion, and she was doing her housework and caring for two children. She was faithful to treatment, generally coming every week, and six months later it was recorded that the lump had markedly diminished, being about an inch in diameter and very shallow, and with absolutely no pain. Six

months later still practically nothing could be felt. About a year or more after her first visit three physicians were told that she had had a breast tumor, and all of them, feeling the breasts, decided that it must have been in the left breast instead of the right, as there was a slight chronic mastitis there. She had been pregnant and gave birth to a dead-born child. When seen recently, nearly two years after the first call, there was nothing to be felt in the right breast, but still a little chronic mastitis in the left, and a fourth physician decided that the cancer must have been in the left breast.

One of my assistants recently reported to me a very similar case, where the lump had disappeared under medical treatment and after a year the same mistake was made by a doctor examining both breasts who decided wrongly as to which breast had been affected.

Case II.—Miss C. M. S., aged thirty-five, seen first January 15, 1917. Six months before she had a severe blow in the right breast which soon enlarged and was painful; it had been poulticed and iodex applied. When first seen there was a lump, the size of an English walnut, quite well defined, and with darting pain; no axillary glands were felt, though small enlargements developed two months later as she had neglected the treatment given. After a few weeks of rigid treatment the breast was softer, with some pain and drawn feeling. Two months later the right breast felt almost the same as the left, though there was still a sharp margin in one place. When last seen, about eighteen months after the first, the right breast was normal, but a little mastitis caking existed in the left breast, and she had had some little feeling in both breasts during menstruation. This was a difficult case to handle, as she had much care, work, and trouble keeping a boarding house, with her mother sick at times. She had much gastric disturbance and was much constipated before treatment.

Case III.—Miss G. D., aged forty-five, was under treatment for eczema, which had about disappeared, when on January 22, 1917, she called attention to a lump in the left breast which had existed for six months or more. It was just above the nipple, the size of an egg, with sharp edges and some adherence to the skin, with some glandular enlargement, and sharp pain occasionally. This patient has been under frequent observation and constant treatment now for almost two years, and while the lump has not wholly disappeared, it is not one-half the size, is softer, and without the sharp edges, and the glands can hardly be felt; there is rarely any pain, except after much exertion. She keeps her color and weight well, and has been active as an attendant upon an elderly lady. There is every reason to believe that the absorbing process will go on, as she is very faithful to treatment, and that ultimately the trouble will disappear entirely.

Case IV:—Mrs. G. K. L., aged fifty-nine, received a slight blow on the inner upper quadrant of the left breast and immediately felt a peculiar sensation, which passed off, and the lump was not noticed until four years ago. Since then the breast has felt heavy and gradually the mass increased in size, until it was about 3½ inches in diameter, hard and characteristic, when first seen, with some enlarged glands in the axilla. She had been under a partial "green card" diet for a year. Being placed on very strict diet, with medication, at the end of three months the tumor had diminished more than one-half in size and was much softer, as verified by another physician. She had gained 4 pounds from the first, with good color, and felt better than she had for a long time.

Case V.—Miss L. M., aged fifty-five, a recent case, presents points of interest. Fourteen months before her visit, November 4, 1918, she noticed a small lump in the right breast, which had been kept secret until a week previously. It was painful from the first, the pain increasing as the mass grew, until of late it had caused many sleepless nights. When first seen there was a large tumor, 2 or 3 inches in diameter, in the inner upper segment, near the nipple, with a purplish-red protruding area an inch in diameter, ready to ulcerate. The whole breast was tense, and the axillary glands were enlarged and painful on handling; there was no supraclavicular adenopathy. The almost immediate relief to many symptoms from a strict vegetarian diet, according to the "green card" previously referred to, and appropriate medical treatment, was surprising. In a week the tenseness of the breast had materially lessened and the pain was decidedly less. After ten days the lump was less hard and the axillary glands less prominent. A week later the purplish color had almost gone, ichthyol having been applied frequently from the first, and the axillary glands had diminished one-third or more, as verified by a physician who watched the case with me. While the final result of such a large tumor cannot be surely foretold, if improvement should be arrested I might have the offending mass removed by the Strobel chemical extirpation, as was done in the case next to be mentioned. This avoids severing blood-vessels and lymphatics, which are sealed by the caustic, and the process is not commonly followed by the recurrence so common after removal by the knife.

Case VI.—Mrs. L. H., aged thirty-six, came under observation and treatment September 20, 1918. She had had two children, one twelve years of age, who had been nursed three months, and one child six years old. She had much milk in the left breast, but the nipple was sore for two weeks and the baby was weaned. Her mother had died of malignant disease of the bladder at the age of fifty-five. Fourteen months previous to her visit she had first noticed a lump in the left breast, the size of a marble, which had increased gradually, but was supposed to be doing well under vegetable diet and various medications, until she had a severe blow on that breast two months before coming for treatment; since that time it had increased rather rapidly, with shooting paints extending from the left arm. When first seen there was a large hard mass in the upper outer segment of the left breast, 2 or 3 inches in diameter, adherent to the skin, with a moderately reddened area an inch or so in diameter. The saliva was acid and the urinary excretion insufficient in its solid ingredients. Under active dietary and other treatment it was recorded one month later that the breast was less swollen and less red, but that she still had considerable pain the previous week, during the menstrual period, and that the axillary adenopathy seemed more pronounced, and one or two enlarged supraclavicular glands were found a week later. She had, however, done well physically, had gained in flesh a little, had good color, slept well without pain, but had some darting pains in the daytime.

In view of the size of the tumor and her general nervous condition, and the extreme tediousness of its medical removal, I decided that it would be wiser to have the breast removed by local caustic treatment, as I have had a number of my cases so treated at the New York Skin and Cancer Hospital by Dr. Strobel, with good results. The process was begun on October 31, the last application of the plaster being made on November 9. On account of the difficulty in reaching and removing the enlarged axillary glands skin-grafting was not done until November 26, when there was still some sloughing to take place in the axilla. The grafts took perfectly over the breast area, giving a smooth, healthy surface, leaving still some raw space in the axilla to be treated later. The slough there finally separated on December 9, and skin-grafting was done December 13 and took well.

One or two cases may be mentioned to illustrate what can be done for patients where the disease has recurred after one or more surgical removals.

Case VII.—Miss H. K., aged forty-five, first seen December 17, 1917, had noticed a lump in the right breast in April, 1915; this was removed surgically within three months, with a good axillary operation the following July 14. About the middle of June, 1917, she noticed a lump in the left breast, in the outer lower segment. When seen there was a mass the size of an egg, hard, with some irregular nodosities; the glands along the pectoral muscle were enlarged, with some doubtful axillary adenopathy. She was always constipated and the saliva was acid; the menopause had not yet occurred. Placed on a strict diet and medication, she has

been very faithful, though living in a distant city, and coming to New York many times up to the present. The tumor is materially smaller and softer, and no adenopathy can be detected. When we consider what would ordinarily happen in such a case in a year and contrast her present condition, when she says that she "feels very well indeed," there is certainly reason to believe in the internal relations of cancer.

Case VIII.—Mrs. B. E., aged forty-nine, had the right breast removed, by a very complete axillary operation for adenocarcinoma, by one of the leading surgeons in New York, on September 27, 1916. She had never thought of the breast until five or six weeks before the operation, the tumor beginning the size of a walnut and growing rapidly in extent, with glandular enlargement. Four months after the operation, January 30, 1917, she came under observation and treatment with recurrence in the axilla, a swollen arm, paining and aching, and some areas of tenderness. She had long had persistent constipation, depending on cathartics all the time; she had borne three children, twenty-one, twenty, and thirteen years of age; the menses had ceased five years. For two years she has been a most faithful patient, coming almost weekly from a neighboring town, except during the summers, when she was far away and wrote occasionally. The course of this case has been interesting but not satisfactory, showing how deeply seated is the constitutional error which first manifests itself in a single lesion in the breast, and that the early and perfect removal of this could not arrest its progress.

During these nearly two years, with complete and careful carrying out of all dietary and medicinal measures, there have been repeated manifestations of the cancerous dyscrasia, in the way of cutaneous nodules and erythematous patches, with also axillary and supraclavicular adenopathy, and latterly bone involvement in the sternum, and cough, indicating internal adenopathy. But, on the other hand, without this constant and faithful treatment the disease would undoubtedly have had a lethal ending long ago. Moreover, until quite recently she has had no pain to speak of and has never taken a narcotic, and has been active and with a good color. For the last few months she has had much anxiety in regard to her two sons, who are at the front in France, which has had a manifest effect on the disease. During the treatment she has had many applications of the *x*-ray to glandular enlargements, and also latterly radium emanation insertion in some of them and radium to the sternal lesion by a most competent operator. Although the total results have not yet been satisfactory, there is hope that with the nervous strain removed by the shortly expected return of her sons from the war she may respond better to further treatment.

Latterly, however, the cough and shortness of breath increased, and on November 29, 72 ounces of fluid were drawn from the pleura. This exhausted her, as I learned by letter from her husband in a distant town, and matters look serious. He added, however, "I am fully convinced that you added considerably to her life, in comfort and length of days."

Cancer of the Uterus.—Three cases of cancer of the uterus were recorded, one of which was seen only once in consultation, very far advanced and under large doses of morphine for months. The other two, totally inoperable and ultimately fatal, exhibited in a striking manner the great value of proper medical treatment.

Case IX.—Mrs. N. R. M., aged fifty-five, was first seen December 27, 1917. She had been examined by Dr. John G. Clark of Philadelphia and others, with the diagnosis of inoperable cancer, with not over six months to live. There was a "great ragged crater, extending back to the rectum and forward almost into the bladder, and laterally to the pelvic walls." She was then examined by one of the surgeons of the New York Skin and Cancer Hospital, where she was treated, with confirmation of the condition, and a very hopeless prognosis was given of but few months to live. She had two children, thirty-five and thirty years of age, and the menses were normal up to their cessation three years ago, but nine months ago she had a profuse watery vaginal discharge and occasional bleedings since, with pain over the pubis. On entering the hospital she had an offensive bloody discharge. She had been habitually constipated and the saliva was found to be very acid.

She was treated, as were the other uterine cases already favorably reported, dietetically and medically, and with a vaginal douche of very hot water, 1 pint, containing half a teaspoonful of carbolic acid and two of borax, thrown in deeply and strongly with a Davidson's syringe, night and morning, and later also at noon. Within about a month there was a marked improvement in her looks and feelings. The douche came away clear, with no blood, only a little cloudy with a few shreds, and with no odor. The urine, which had been scanty, increased to quite a normal amount and character, and the saliva became neutral; she slept well most of the time, without much pain in the pubic region. She was given, in addition, capsules of the pyrophosphate of iron and her color, weight, and vigor improved, so that, in the light of the other cases, it seemed as though she would pull through. But the dullness above the pubis slowly increased, with bowel obstruction and tympanites, the urine became scanty and albuminous, with swollen legs and feet, and other signs of serious kidney involvement. The blood, which had been fairly normal, showed great degeneration, with only 50 per cent. hemoglobin, 1,350,000 erythrocytes, 13,000 leucocytes, of these 70 per cent. polynuclear, 5 large mononuclear, 50 small mononuclear, 4 transitional, and 1 eosinophile. She finally passed peacefully away in coma on August 16, without requiring or having taken a particle of morphine or other hypnotic, except a small dose of chloral and bromide occasionally at night when sleepless. She had some sciatic pain which was helped by the free use of a coal-tar analgesic.

When we consider the course of the disease in this patient, with her constant hopefulness and comfort during these eight months instead of six months or less, as compared with the agony often suffered, especially in cases recurrent after operation and the amount of morphine often taken, there is certainly reason for believing in the value of the proper constitutional treatment of cancer. With the enormous infiltration of the abdominal viscera and the great ulceration, the case was, of course, hopeless from the beginning.

Case X.—Mrs. T. F. V., aged sixty-four, first noticed bleeding from the vagina three months before her first visit, November 23, 1917. She had had pain in the back a little while before, and some bleeding every two weeks and for a day or two at a time. She had not felt well since June and had lost 20 pounds, weighing 107 when first seen. She had been examined by a surgeon two weeks before coming from Maine and pronounced to have inoperable uterine cancer. She was examined here by a gynecologist, who found extensive cauliflower ulceration of the cervix, with the uterus of great size. She had had six children, thirty-eight to twenty-eight years of age, and the menses had ceased twenty years ago. She was always constipated, the urine had always been scanty, and the saliva was very acid. The urine was of a low specific gravity, contained a moderate amount of albumin, and the urea low. Under careful dietetic and medical treatment, with the same vaginal douche as in the preceding case, she improved greatly, gained 2½ pounds in weight, and "felt like a different person," within a month, coming frequently to the office. She had relatively little pain, never requiring an opiate, and two months from the first it was recorded that she "felt freer from pain during the preceding week than for weeks or months." The douche came clear and without blood. The urine continued of low specific gravity, but occasionally without albumin, and the saliva continued very acid. Two weeks later she had a strange attack, with suppression of urine, and she became somewhat irrational and was moved to the hospital, as she could not be well cared for in a boarding house. This condition continued for a while,

but two weeks later she was perfectly rational and wanted to go to her home in Maine; she said she had no pain. She was taken home and died peacefully twenty-five hours after reaching there, on March 21, 1918. She thus lived almost four months in comparative comfort, not taking a particle of morphine or other hypnotic, and died without pain, sleeping peacefully, as reported by letter. The case was, of course, hopeless from the beginning.

Cancer of the Stomach.—Five cases were recorded, all males, aged 65, 58, 56, 44 and 43, but only one of them was treated; one was seen only once in consultation, far advanced, who died not long afterwards; two were seen only once, and one by correspondence.

Case XI.—W. B., aged fifty-six, had been sickly and not working for a year before his first visit, August 30, 1916, and had seen many physicians and surgeons, all of whom diagnosed the trouble as cancer of the stomach. He had had pain in the epigastrium for a long time, with swelling and hardness. On examination there was dullness on percussion over the pyloric region, and a mass could be felt. He had long been constipated, with coated tongue, and was very weak, having lost many pounds. Placed on a rigid diet and strict regulations as to mastication and living, with medication, he improved greatly, looking and feeling much better at the few visits he made from another city. Seven months later I learned from his brother-in-law, who had brought him, that the patient was very well and was working again. I realize that the diagnosis is very difficult in these cases and that he may not have had real cancer, but his whole appearance and the clinical symptoms, with his cancerous cachexia, loss of weight, etc., indicated the probable correctness of the diagnosis made by several medical men, and the results were certainly most satisfactory.

Cancer of the Rectum.—Two cases were recorded, one in a woman aged 55, and the other in a man aged 42, the latter only being treated. The former had had an artificial anus made, and subsequently intestinal anastomosis for inoperable cancer of the rectum, and was seen only once.

Case XII.—Mr. R. G., aged forty-two, came for treatment June 13, 1917. Two and a half years before he had had an operation for ulcer of the stomach, and had had no trouble until November, 1916, when he was given Russian oil for obstinate constipation. About a month before his visit he was seen by a surgeon of prominence, who diagnosed cancer of the rectum, verified by microscopic findings, and advised an operation, which he refused. When seen he was rather thin and haggard, having lost a good many pounds, pulse 92 and poor, tongue badly coated. His sleep was disturbed by having to get up three or four times for small, thready bowel movements, of which he had from twelve to fifteen in twenty-four hours. On examination there were no external signs of disease, and digital examination revealed little, the disease being higher up. Under dietary and other treatment the bowel movements were soon reduced to four in the twenty-four hours, one of them at night, but still watery and generally with some blood, but no pain. Six months later he was often having formed movements of good size, and had been better in every way the preceding month than for a year, with only slight pain in the rectum occasionally. There was still a little blood passed, although on April 12, after an absence of a month, it was recorded that there was no blood in the passages. When last seen, nearly a year from the first visit, he was in about the same condition; he had been steadily at work in a dry goods house all the time while under treatment. In view of the unsatisfactory results commonly obtained by operation, and the distressing condition of the patient after colostomy, the results in this case may be considered satisfactory.

Cancer of the Prostate.—Two cases were seen, aged 74 and 54; the first one was seen only once.

Case XIII.—B. S., aged fifty-four, had long had enlarged prostate, with frequent urination day and night. He had lost flesh, especially during the six months preceding his first visit, October 26, 1917. He had then an earthy, cachectic look, was thin and depressed. On examination by a surgeon the prostate was enlarged and the inguinal glands on both sides were greatly affected, forming great masses visible to the eye, there being no lesions on the penis. Under the "green card" diet and medication there was a very great change in a few weeks. The patient felt and looked very much better. The glands in the groins had subsided very noticeably, and shortly after they had quite disappeared, the cachexia was gone, and he had not an ache or a pain. He was lost sight of, and although written to did not respond. As in cancer of the stomach, a clinical diagnosis is often difficult, but such a result is certainly preferable to surgical interference, with all its uncertainties. A notice in the daily papers recently stated that he had died very suddenly.

Cancer of the Kidney.—One case has been under my constant care for two years and the results illustrate well the value of continued constitutional treatment.

Case XIV.—Mr. H. H. B., aged fifty-five, has been indisposed for a year, his color was bad, and work difficult to accomplish. On August 25, 1916, he passed blood in the urine, and the next day red blood, and also coagulated, with much pain in the back. The x-ray was said to show nothing, nor cystoscopy, except blood from the right kidney. This latter was removed on September 1, in another city, and found to be enlarged four times in size, weighing over 2 pounds, and shown to be cancerous microscopically. He made a good recovery and had no pain while in bed three weeks, but on walking had pain in the left side, increasing toward afternoon and rendering life miserable up to his coming under treatment January 30, 1917. The pain generally ceased on lying down at night. He weighed 173½ pounds, was a large eater of meat and was very fond of milk and eggs. He had never had any restriction of diet, nor directions or other treatment of any kind, only the operation.

Under strict vegetarian diet and varied treatment at frequent consultations, with voluminous notes, he has for two years been able to do his work, has gained 14½ pounds in weight, and for long periods has been free from pain, although there are times when he has pain over the left kidney. Recent letters show that he was "doing normal work" and "stands well the hardest strain," "felt better than for years," and "never had so good a color or circulation." The urine has been watched, measured daily all the time, and frequently analyzed volumetrically, and has commonly averaged over 50 ounces daily; the various ingredients are generally about normal, except that the urea is low, owing to the vegetarian diet. He has been, and I believe will be, very faithful to treatment, which has certainly prolonged his life and usefulness, and given great comfort and ease. How long it will be necessary to continue active treatment it is difficult to say; a relapse to his former method of living and entire neglect of protective treatment might naturally be expected to induce again a serious involvement of the remaining kidney. He has, of course, never taken a particle of morphine or other hypnotic, the pains occurring at times being largely relieved by the frequent use of a coal-tar analgesic.

Cancer of the Bladder.—One case of this has been under prolonged treatment with eminently satisfactory results.

Case XV.—Mr. G. W. H., aged sixty-eight, had been under my care for a number of years, for various difficulties, when on March 27, 1914, he brought two specimens of urine with clots of blood and a considerable amount of albumin in the evening sample, and was seen the next day. There had been no especial pain in the back, nor on passing urine, which had cleared since. Three days later he was again passing blood and was feeling weak, and thought he had lost 2 pounds in weight. He had to urinate every two hours, twice at night; the blood appeared mainly at the end of the urination. Blood pressure 160, systolic. On April 2 he was

cystoscoped by Dr. A. R. Stevens. The bladder mucosa was found to be normal, except near the left urethral orifice. Just above this there was a small, nodular, well defined, sessile mass, with small blood-vessels over its surface, pretty typical of carcinoma of the bladder wall. Radical excision was advised, or else fulguration. Declining these very positively, he was treated medically for a month, when he yielded, and on May 7 Dr. Stevens treated the lesion by fulguration, which was repeated on May 22. On August 5 there was some recurrence seen, in a slight crescentic mass, which was destroyed by high frequency current, with again a slight operation on August 10. On October 22 he was cystoscoped and no sign of recurrence was seen, only a scar. On February 23, 1915, there was a small regrowth, not one-half former size, which was treated with the high frequency current, and again slightly on March 2. He has been repeatedly cystoscoped since that date, up to the present time, by three urologists, and there are no signs of recurrence now nearly five years from the first symptoms observed.

The patient has been under constant medical treatment, with strict diet all this time, for various troubles attending high blood pressure, which has reached 200 systolic, but is commonly kept under control to about 150 systolic and 80 diastolic. On December 22, 1916, Dr. Stevens found a "large, elastic prostate (not carcinoma), which, however, seemed to cause no special symptoms until December 7, 1917, when blood clots were found in the urine, which have continued to appear much of the time ever since; these clots show only blood and fibrin, and no evidence of new growth tissue, as reported by Dr. Jessup. On repeated cystoscopic examinations no trace of the original or any other trouble in the bladder has been found, but "an adenomatous hypertrophy of the prostate and a slight bleeding from the prostate portion of the urethra." This was confirmed by two other urologists. During all this time under strict regimen and varied medication he has maintained his usual health, color, and weight, and pursued his usual business.

Cancer of the Buccal Cavity.—Five cases were observed, four males, aged 47, 48, 59 and 72, and one female aged 44; of these two were of the right upper jaw (not sarcoma), two of the tongue, and one of the tonsil. There were also three cases of sarcoma, two of the left upper jaw and one of the right lower jaw, besides three other cases of sarcoma located elsewhere. The cases of carcinoma of the jaw were seen only in consultation. One was a terrific post-operative case for which little or nothing could be done. The sarcoma cases were also seen in consultation, and one was advised to see Dr. Janeway for radium treatment. The woman with cancer of the tongue was seen once in consultation, the other case, though rather recent, and also the one with cancer of the tonsil are worthy of mention.

Case XVI.—Mr. K. M. A., aged fifty-nine, seen September 11, 1918, first noticed an irritation of the right side of the tongue, from a broken tooth, in May; and on May 11 it was operated on, with a knife and healed so that he went to work on May 20, with no pain for three weeks. It then began to ulcerate and a knife was again used and it was cauterized on August 5, and he left the hospital August 11, five weeks before his visit; since that time the trouble has been increasing rapidly, until when first seen the tongue was enormous, filling the buccal cavity, with a large ulcerative, hard patch, an inch and more on the side, with sharp edges; the submaxillary glands were very large, hard, and matted together, and the case was considered wholly inoperable by the surgeons whom he had seen. He had always smoked much, but took little alcohol, coffee, or tea. The saliva was very acid, the urine contained much indican, also oxalates and phosphates.

Being placed on the "green card" diet, with absolutely no smoking, alcohol, coffee, or tea, and with the mixture of acetate of potassa, nux vomica, cascara, and extract of rumex, the improvement began almost at once. He also used a mouth wash of a saturated solution of bicarbonate of soda, diluted one half, held in the mouth some minutes, a quarter of an hour before and also after taking food. He could take only liquid food, having great difficulty in swallowing.

By the end of three months the change was most remarkable. The ulceration had ceased at the side of the tongue, which had greatly diminished in size, though still hard. He swallowed much better, the jaws opened much wider and he could chew some, and the glands beneath the jaw were smaller and less adherent and movable, as was verified by two physicians. He remarked the "great improvement" in his condition and his wife said "the change from the first is marvelous." He still complained of some pain in the neck, running up to the head, but he has never taken any morphine or anodyne. When seen later, very recently, the improvement was still more marked. It is, of course, too early to claim a cure, but with continued proper treatment, of various kinds, there is every reason to believe that the progress toward that end will continue. This case illustrates well the harm from curetting and cauterization, which stimulated an ordinary slight ulcerative process from a rough tooth into a malignant disease.

Case XVII.—Mr. F. F., aged seventy-two, came under observation and treatment on October 2, 1918. For three months he had felt a pressure of something wrong on the ride side of the throat, and on September 3 had had some sort of an operation from within, the nature of which could not be determined. He had seen many physicians and surgeons, who advised a complete operation from the outside, which was refused. A Wassermann test had been made and found negative. On examination the right tonsil was found to be the seat of an ulcerative process. half an inch or more in diameter, very hard to the feel, with sharply defined hard edges, and considerable inflammatory action of the surrounding parts, reaching over almost to the left tonsil. The glands beneath the right jaw were greatly enlarged, the size of a large walnut, but rather movable. The saliva was very acid. He had been in the habit of taking beer twice daily, and smoking, which, of course, were stopped. Placed on a rigid vegetarian diet, with the same mixture as in many other cases, and the soda gargle, held in the throat a good while before and after each meal, he began to improve from the first. Within two months the ulceration had about ceased and much of the adjoining inflammatory action subsided. The hardness had largely disappeared, though the edge was still hard. He remarked, "I feel all right and have nothing to complain of." The gland in the neck had diminished to the size of a small almond. A little later it was recorded that there was still slight marginal hardness, but superficial, in the diseased area, the gland was still smaller and freely movable, and he said that he felt "perfectly well," "find no complaint of any kind."

In this article and in the volumes above referred to are recorded over thirty cases of cancer, among many others, in which the benefit of a properly regulated medical treatment was clearly manifest. Some of the earlier breast cases had been followed from 13 to 16 years, remaining perfectly well without operation; others were well from three to five years, and the two uterine cases reported in the second volume remain for almost three years with no recurrence, being still under treatment. The more recent cases have shown such steady improvement that it can hardly be doubted that, if they remain still faithful to treatment, they will ultimately recover. The fatal cases were mostly post-operative, but they also exhibited strikingly the benefits from this treatment in prolongation of life with great comfort. As far as I can learn from my notes none of the patients required or received any anodyne from soon after the time that they began treatment. When all this is compared with the ordinary course of cancer cases it does seem

that we are on the right track concerning the treatment of cancer.

It is not claimed that the goal has been reached, or that the details of this line of treatment are complete. Laboratory and clinical study on the blood plasma, as well as on the secretions and excretions, will undoubtedly elaborate more perfectly the best plan of dietary and other treatment, and as other observers follow this plan of treatment there will doubtless be found a gradual reduction in the mortality of cancer greater even than has occurred in New York City during the first half of 1918. It is surely to be hoped that as "the real cancer problem" is fully solved there will be, under proper constitutional treatment, the same lowering of mortality that has occurred in tuberculosis under wise medical treatment. And as correct views of living prevail, the morbidity of cancer will decrease with its mortality.

OXYGEN TENSION IN ITS RELATION TO THE MENINGOCOCCUS.*

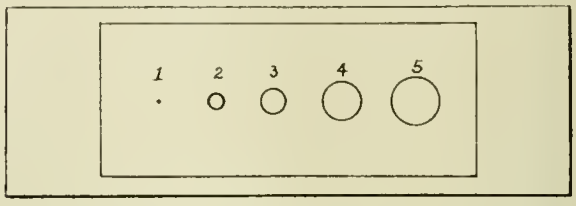
By First Lieut. J. H. St. John,
Medical Corps, U. S. Army.

Wherry and Oliver[1] found that certain organisms, particularly the gonococcus, were adapted to growth in an atmosphere of reduced oxygen tension. Cohen and Markle,[2] in an article on the effect of reduced oxygen tension on the growth of the meningococcus, called attention to their findings of better growths resulting when this organism was cultured in connection with the *Bacillus subtilis*. Cohen, in a recent article,[3] again reports favorably on the method, and suggests that the subject be investigated. Since the method of culturing the meningococcus in an atmosphere of reduced oxygen tension promised a means of uncovering more carriers than are ordinarily found, and because of its probable practical application in diagnosis, it was deemed of moment to undertake cultural tests in an effort to determine its value and practical application.

In these tests the sources of our cultures were: (1) Chronic carriers of the meningococcus; (2) stock cultures; (3) spinal fluids. In the first instances two men in isolation at Washington Barracks, D. C., were selected as being representative of this group. One (Fullam) yielded a Parameningococcus and the other (Graves) gave a regular (normal) type meningococcus. From both men positive cultures were invariably obtained. The stock cultures used were old strains of type, regular and para, furnished by the Rockefeller Institute. Spinal fluid strains were not used after the third transplant.

Stock cultures gave so profuse a growth under the usual conditions that it was difficult to form an opinion as to the value of the experiments. Spinal fluids were not obtainable in the number desired, and therefore the chief value of this report centers in the results obtained from the experiments conducted with the chronic carriers.

The method of utilizing the carriers was as follows: The nasopharynx was swabbed in the usual manner and the swabs carefully cleared of their charge in a very small quantity of broth. Two small loopfuls were streaked across the surface of laked rabbit blood agar plates. The medium used in the experiments was all from the same lot, and poured in a manner to insure as near as possible a uniform thickness. The plates were compared at the end of eighteen hours' incubation and the selected isolated colonies used in the comparison tests were later subjected to the routine tests for the identification of the meningococcus. In the method of comparison we took into consideration the general impression conveyed by the growth, the depth of the colonies, and their diameter as compared to a scale made on a glass slide as per diagram:



In order to obtain a working basis it was thought best to undertake a few general experiments. Therefore, the inoculated plates made from the nasopharyngeal secretion were cultured in an atmosphere of reduced tension obtained by: (1) Replacing the air in desiccators by (*a*) hydrogen, (*b*) carbon dioxide; (2) (*a*) reducing the oxygen content by growing in sealed chambers along with plates of *B. subtilis*, (*b*) pyrogallate method; and (3) reducing the actual air content by means of the vacuum pump.

From these preliminary comparative experiments it was concluded that better growths resulted, though not invariably, by growing with *B. subtilis*, and by partially replacing the air content of the desiccators with hydrogen. The carbon dioxide replacement method appeared to inhibit growth when more than 50 per cent. of the air content had been displaced. The medium exposed to an atmosphere partially composed of this gas assumed a methæmoglobin hue, probably due to a change in the reaction of the medium, resulting from the absorption of an impurity carried over from the generator. Reduction in the actual air content by means of the vacuum pump did not improve the growth.

It was noticed on plates giving better growths, particularly in connection with *B. subtilis*, that a considerable amount of moisture collected on the surface of the medium. Since it was known that moisture was an especially favorable factor in the production of good growths of the meningococcus it was thought that perhaps its presence might partly explain the better growths resulting on the plates incubated in closed chambers. It was therefore decided to conduct experiments with the separate methods of reducing oxygen tension, and add to our control, plates incubated in a sealed desiccator to which a little water had been added in order to saturate the contained atmosphere, and thus prevent surface evaporation. A report on these experiments follows:

Partial Displacement With Hydrogen.—Method: Hydrogen generated in a Kipp apparatus was allowed to partly replace the air in Novy jars in which plates containing the meningococcus material had been placed for 5, 10, 15, and 20 minutes. At

*From the Department of Pathology, Army Medical School, Washington, D. C. Published by permission of the Surgeon General, U. S. Army.

the end of eighteen hours' incubation the oxygen content was determined and the growths compared. The following table is taken from our notes as typifying our results:

	Carriers—Fullam.	Carriers—Graves.	Determination of oxygen content.
B. subtilis	4	4	3.8%
Air plates	2½	3½	
Moisture	4	3½	
Replacement with hydrogen for:			
5 minutes	3	3	15.6%
10 minutes	4	4	13.1%
15 minutes	2	2	4.2%
20 minutes	2	2½	1.2%

The numerals in the above table represent the diameter of the colonies as compared to the scale previously described. The general impression received was that the moisture plates were as good as the best growths obtained, and although good growths were obtained in the open they were inferior to the *B. subtilis*, moisture, and hydrogen plates when not more than 50 per cent. of the oxygen content of the latter had been displaced.

Reduction by Means of the Bacillus Subtilis.—The method consisted in filling desiccators with freshly inoculated plates of *B. subtilis* and meningococcus material in varying proportions, sealing tightly, incubating, and at the end of eighteen hours determining the oxygen content.

The following table may give some idea of our findings:

	O_2 14.1 Per Cent.	O_2 5.4 Per Cent.	Air.	Moisture
Fullam	3	3	3	3
Graves	3	4	4 few	5

Although very little difference existed in the diameter of the colonies selected, the general appearance, number and depth of the colonies led to the conclusion that plates grown with *B. subtilis* and by the moisture method were better than plates grown in the open.

Reduction of the Air Content.—The method used was to reduce the atmospheric pressure in desiccators, in varying degrees, and measuring the degree of vacuum before and after incubation. The following table is self-explanatory:

Incubation—Before.	Incubation—After.	Incubation—Average.	Appearance of plate.	Size of selected colony.
24½"	23½"	24"	R. 60, no growth.	
			Fullam, growth.	Very small.
			Graves, growth.	Very small
14½"	13½"	13"	R. 60, good growth	2
			Fullam, growth	Very small.
			Graves, growth.	Very small.
8"	6"	7"	R. 60, good growth.	2
			Fullam, good growth.	1
			Graves, good growth.	2
20½"	21½"	..	R. 60, luxuriant growth.	2
			Fullam, luxuriant growth.	2½
			Graves, luxuriant growth.	2
Air plates.			R. 60, luxuriant growth.	2
			Fullam, luxuriant growth.	2½
			Graves, luxuriant growth.	2
Moisture plates.			R. 60, very luxuriant growth.	2
			Fullam, very luxuriant gr'th.	3
			Graves, very luxuriant gr'th.	3

From experiments conducted along this line it was concluded that varying dgerees of vacuum did not favor the growth of the meningococcus, but in fact there was even a noticeable tendency for the vacuum to retard growth. When the vacuum was lost during incubation the growths were much better.

Partial Absorption of Oxygen by the Pyrogallate Method.—The test plates were placed in desiccators containing, in separate dishes, solutions of sodium hydroxide and pyrogallic acid in varying proportions. After sealing the desiccators the solutions were allowed to mix. After eighteen hours' incubation the oxygen content was determined and the growths compared. The following table is typical of our findings:

	O_2 9.5 Per Cent.	O_2 15.3 Per Cent.	Moisture.	Air
Fullam	1-2	No growth	3	1-3
Graves	2-3	No growth	4	3-4

The colonies developing under the pyrogallate method were noticeably weak. The moisture plates were better than the air plates.

In addition to the above comparison tests several spinal fluids were subjected to comparative studies, using all the above methods at the same time. While it appeared that the methods of growing in connection with the *R. subtilis*, and by partly replacing the air content with hydrogen, gave better growths than either in the open or moisture chambers, our series is as yet too small to allow us to draw definite conclusions as to the value of the different methods when culturing spinal fluids.

During our experiments we received several cultures that had not been transplanted more than two or three times. They were subjected to the following: On one-half of a plate the culture was streaked, and on the other half *B. subtilis* was heavily inoculated. The petri dish was sealed with paraffin. Controls were made by sealing a plate inoculated with the meningococcus, and also by culturing in the usual manner. In every instance tests made in this manner gave better growths in the sealed chambers with or without the association of the *B. subtilis*.

In a review of the growths obtained by the moisture method and the ordinary manner of cultivating the organism, the following table is given:

Date.	Graves—Moisture.	Graves—Air.	Fullam—Moisture.	Fullam—Air.
August 2, 1918.	3	3	2	2
August 3, 1918	3½	3½	4	2½
August 4, 1918	3	2	1	2
August 6, 1918	3	3	1½	N.G
August 13, 1918	5–6	4	4–5	2½
August 11, 1918	4–5	3	3	3
August 10, 1918	2½	2	2½	2
August 12, 1918	1	3	3	3
August 11, 1918	5	4	4	3

The general impression recorded, with few exceptions, was that plates grown by the moisture method were much better than those grown in the open.

Summary and Conclusion.—A reduction of the oxygen content in varying degrees by means of the pyrogallate method did not favor the growth of the meningococcus. Reduction by replacement with hydrogen when the determined oxygen was not less than 10 per cent. did yield good growths, but not materially better than the moisture controls. Better growths resulting from an association with the *B. subtilis* were without regard to the oxygen content—a 4 per cent. oxygen content giving as good results as a 15 per cent. content. It seems likely that an organism delicately susceptible to the oxygen content would show some variation in growth within this wide range. A comparison of the *B. subtilis* and hydrogen methods shows that when the oxygen determination of the latter was 4 per cent. a poor growth resulted, while a 4 per cent. content of the former gave a very good growth. A 15 per cent. content, however, in both methods did yield better growths. It is apparent, therefore, that hydrogen in per cent. great enough to cause a reduc-

tion in oxygen content to 4 per cent. exerts an inhibiting influence on the growth of the meningococcus, and for this reason it cannot be fairly compared to results obtained with the *B. subtilis* method.

It would therefore appear, especially in the light of moisture controls, that the oxygen tension factor is of minor importance. Provisionally accepting this conclusion, one must turn to other factors for an explanation of the better growths resulting under the conditions attending a reduced oxygen tension. It is a matter of common observation that the meningococcus is especially sensitive to the degree of moisture and reaction of the medium on which it is cultivated, and it is probable that the explanation of good growths when the oxygen tension method is employed, will be found in one or both of these factors. When cultures of the meningococcus are developed in an association with *B. subtilis* the attending conditions cause a collection of moisture on the meningococcus medium. This is especially noticeable when compared with a control in air. That the moisture factor should be taken into consideration when experiments of this nature are undertaken is readily appreciated when moisture controls are set up in the manner previously described. Apparently, from the literature on the subject of oxygen tension, especially in several recent articles, the moisture factor has not been given the prominence it deserves.

The reaction of the meningococcus medium may be favorably influenced by certain gases evolved by the growing *B. subtilis*, but this consideration is also minimized by comparison with moisture controls.

In conclusion it is suggested that the retention of moisture in the media used for the cultivation of the meningococcus is probably a more important factor than the oxygen content of the incubation atmosphere. It is not necessary, however, to cultivate the meningococcus in closed containers, as the same end result is obtained by giving more consideration to the water content of the media and to the prevention of surface evaporation during incubation. This latter may be accomplished by exposing the incubator air to large surfaces of water placed in shallow pans. This simple procedure has been adopted by the Army Medical School, and better cultural results are obtained.

No More Wassermann Reactions.—It is said that the Société de Biologie has officially done away with the expression "Wassermann Reaction," which is to be known only as the Sigma Reaction. No reason is given for this change.—*Pathologia.*

Ration of German Prisoners in France.—Ramond and Petit give this is as follows: 600 gms. good bread; 87 gms. fresh meat; 1 kilo potatoes; 140 gms. dried legumes; 30 gms. green legumes; 80 gms. rice; 10 gms. fats. In Austria the French prisoners were properly fed but in Germany the ration was deplorable.—*La Presse Médicale.*

RELATING TO THE POSSIBILITY OF PROTEIN SPLIT PRODUCT POISONS BEING FORMED IN MARKET MILK.

By J. M. W. KITCHEN, M.D., M.S.,

EAST ORANGE, N. J.

Long before our present ideas were acquired as to the presence of split product poisons in proteins, I thought that there were poisonous matters formed in milk and accumulated in that fluid as the result of the secretions or excretions of the proliferated infections of milk bacteria. I was chairman of a special committee of the Essex County (N. J.) Medical Society appointed to inquire into the milk situation in Essex County. The late Dr. Henry L. Coit, who is justly entitled to be considered the father of the clean milk movement, was a member of my committee. I told him of my belief in the matter, and asked him to devote himself to the investigation of that phase of the subject. He said he did not believe in it; and as far as I know, did not do any work in that direction, and probably died holding the belief that so far as bacteria had a damaging effect on bottle-fed infants, it was due to the direct influence of the bacteria on the body of the individual. It is an interesting reminiscence that during my student days, which were coincident with those of Dr. Henry D. Chapin and Dr. L. Emmett Holt, and during my work in the pathological laboratory under Drs. Delafield and Pruden, Dr. Coit called at the laboratory to talk over the matter with Dr. Pruden. Dr. Pruden told him that the laboratory had just found its first tuberculous germ in milk, and I understand, turned Dr. Coit over to Dr. Rowland G. Freeman to go into the matter. Most of those I have mentioned have been interested in milk ever since. My old belief held was largely based on the observation that babies in the tenement-house districts did not seem to be much damaged by dirty milk during the winter season when fermentations in milk were at least much restricted; that large accumulations of bacteria would occur in milk that was held at temperatures even much below 50°F.; and that all milk and butter appeared to be contaminated with putrefactive matters. In those days nothing was known, that was generally recognized, of the up-to-date theories relating to these matters. While admitting that specific diseased conditions are caused by and after the invasion of the body by bacteria of the pathogenic types, I hold to my previous conviction that some poisons are formed by germs which proliferate in milk. I even think that milk acids are harmful under special conditions. The observations of 100 years or more have shown innumerable instances of poisoning from decaying organic animal proteins and vegetable matters. When we consider that all protein molecules are apparently synthetic groups that may under disruption, form poison groups, and that milk bacteria synthetically build up and store poison-producing groups from the non-living milk menstruum, we at least have reason for suspecting in this day that what I believed in years past as to the formation of poisons in market milk was underestimated.

How far do late studies and investigations support my belief? It is fair at the start to acknowledge our lack of exact knowledge as to various phases of the subject, and that my special interest in the matter has been that of seeking to evolve a practical plan of operations for applying methods in the production, treatment and distribution of milk, cream and butter, that will secure public supplies of absolutely safe and wholesome milk of high edible quality. In seeking that aim I have taken the "bull by the horns," so to speak, and acted on the theory that as a matter of mere prudence, everything should be done that would be likely in every practical way to render those food products absolutely safe and entirely wholesome, all of which results are easily practically possible. Nevertheless, it is a matter of satisfaction to have sound theories back of our beliefs and practices:

What We Know of This Matter.—1. We know that poisonous matters are produced in some animal and vegetable substances.

2. We are certain that bacteria in some way are sometimes a considerable factor in contaminating milk with more or less poisonous products.

3. We know that a considerable number of milk-borne bacteria are etiological factions in producing specific diseases, and we know that some of the bacteria in milk produce poisonous matters.

4. We know that all bacteria have specific groups in their protein molecules that under certain cleavage conditions will be changed into poisons. We know that bacteria, such as the colon bacillus which does not excrete poisons, if disrupted, dried, and ground, are virulently poisonous, even in minute quantities.

5. We know that such apparently harmless bacteria, under certain disruptive conditions may transmit poisonous matters by diffusion to liquids, which then become virulently poisonous under certain conditions, as by injection.

6. We know that these specifically prepared poisons will kill animals in a time ranging from a few minutes up much longer periods.

7. To know that practically all milk is contaminated more or less with volatile diffusive protein ferment products that are generated in the cow; and that the sebaceous glands of the cow's hide evolve putrefactive matters that are diffused into the milk at the moment of the production of the milk.

8. We know that all milk becomes more or less infected with various types of bacteria at the time of drawing of the milk, some of which are accidental and unforeseen, and some unpreventable.

9. We know that the ordinarily practised methods of pasteurization do not destroy all of the bacteria in milk, including practically all types. We know that undestroyed bacteria or their spores will proliferate and increase in enormous numbers at temperatures at which milk is usually held before and after its pasteurization, and during its distribution and holding at the house of the consumer.

10. We know that milk under all ordinary methods of commercial handling may be subject to infections from the pouring surface of the container, or by working through or passing the peripheral edges of the cardboard seal.

11. We know that in primary infections, bacteria of some types proliferate in prodigious numbers at temperatures much below the temperatures that are usually applied in preserving milk.

12. We know that milk up to a certain time—usually five or six hours after its production—has some constituent matter in it which prevents the proliferation of the primary infections, and we know that the production of acids in milk counteracts or prevents a proliferation of bacteria other than those of the acid-forming types.

13. We know that fermentative processes proceed with such slowness at temperatures below 35°F. and above 120°. that accumulations of protein split poisons in any food are of negligible moment during the usual period of several days elapsing in the transportation and distribution of dead food products.

14. We know that the process of hermetically sealing a food product prevents its infection and oxidization.

15. We know that in addition to hermetically sealing, complete sterilization of a canned moist food in one way or another is essential to the prolonged preservation of a healthful character in that food.

16. We know that a temperature lower than 20°F. is required in butter to prevent its chemical and biological degradation during a long period of its holding.

There are other pertaining matters that we know, that might be related; but the citation of these sixteen facts is sufficient for the purpose of this communication.

The following are some other possible facts which are as yet not determined with certainty:

1. That when the body is invaded by a so-called foreign protein, the normal cells of the body elaborate a counteractive ferment. This is claimed to be a biological law.

2. It is thought that all living cells elaborate ferments that destroy and consume extracellular proteins.

3. It is thought that foreign bacterial invaders of the body excrete matters that may mutually damage both the invaders and the cells that are invaded.

4. It is thought that all bacterial growths are strictly proteins.

5. It is thought that a protein poison is not a toxin.

6. It is thought that a sensitization contributed by a protein matter is not due to a toxic poison in the system.

7. It is thought that the poisonous principles in all the infections are the same.

8. It is thought that some disrupting process is necessary in liberating the poisons that are in proteins.

9. It is thought that the natural process of senility or decay may be such an influence.

10. It is thought that the heat of pasteurization or of incomplete sterilization may be such an influence—a matter of importance in cases where large bacterial contents exist.

11. It is thought that the formation of ferments

by the younger and more active bacteria may cause the dissolution of the older bacterial growths.

12. It is thought that animal blood has germicidal properties for a time at least, and which are assumably due to ozonized oxygen.

13. It is thought that proteins are destroyed during digestion, in the intestines, in the blood, and in the cell.

14. It is thought that proteins not completely digested may, because of that fact, and under other alimentary influences, such as a surfeit of ingested proteins, become disrupted into poisonous groups which act in a poisonous way in the alimentary tract and through general circulatory diffusion.

15. It is thought that the body may be trained to tolerate, and perhaps acquire immunity to all poisons, as is unquestionably more or less the case with nicotine, opium, and some other narcotic organic and non-organic poisons.

16. Inasmuch as it is known that babies require a certain prolonged stage of preparedness in becoming used to cow's milk as a food, it is thought that they may at least acquire some tolerance of poisons formed in milk before its consumption.

17. It is reasonable to conclude that non-living constituents in milk, especially its protein constituents, through the metabolic influence of living germinal upbuilding actions in milk become combinedly changed into molecules that under certain conditions are destructively changed into poisons.

18. The disruption of bacteria may be effected by chemical influence or by the fermentative action of enzymes; and a large amount of poison may be produced from a very small amount of protein substance.

19. The protein poisons quickly destroy life in animals in relatively small doses, and hence it must be assumed that, in nonlethal doses they are capable of exerting a menacing action against the healthful activities of animal life, especially in repeated small doses.

20. Any bacterium is a pathogenic entity when it grows in a medium that has not the power of preventing the growth of bacteria.

21. A preventive power against bacterial proliferation may be: adverse temperature influence, chemical action, or antagonistic ferment influence.

22. While some authorities hold that some living cells may be antagonistically stimulated to produce ferments that will prevent the growth of poison-forming invading bacteria, this protective action does not pertain to non-living forms of matter, such as the menstruum of milk.

23. While milk gains immunity against the growth of some forms of bacterial life through the formation of acids produced in the proliferation of some acid-forming types, if through temperature influence that acidulous immunizing power is not effected, it is obvious that there is a free field for the formation of bacteria and spores of the non-acid-forming types.

24. In breast-feeding, and in the consumption of fresh milk, there is conveyed into the alimentary tract of the individual, a protective, if not immunizing constituent in the milk consumed, that is not conveyed in milk that has lost the protective power.

25. All forms of life undergo senile degradation and disruption, including milk bacteria, with consequent decay unless preservatively influenced.

It appears reasonable to conclude that whether protein split poisons are formed in milk or not, infants and others not protectively immunized against the direct action of destructive changes in market milk, or the poisonous products of destructive changes, should in particular be protected against all such possible poisonous influences. There is no evidence in hand going to show that a moderate pasteurizing heat, will destroy formed ferment products, although it may be effective in driving off some volatile ferment products of a putrefactive character.

So far as cheese is concerned, in which deadly poisons may be formed, it may be assumed that usually the counteractive influences of ferment and digestive changes, and the formation of counteractive harmless types, protects this food from the formation of protein poisons; but we as yet know too little as to this matter to be able to make any definite statement.

It is submitted that with such absolute knowledge as we have, and with other information which seems to be sound, if we thoughtfully consider the subject herein briefly summarized, we are warranted in arriving at the conclusion that not only should milk be obtained from healthy cattle in as clean and uninfected a manner as possible; but that fermentations in it of *all* kinds that are not strictly protective in character and effectuated from a sterilized milk basis, should be *entirely* prevented; that all fresh infections should be prevented; and all possible removable volatile putrefactive constituents should be eliminated from the milk. Yet such protection is *not* fully practised today.

The subject matter here summarized is, of course, only a brief statement excerpted from some of the many highly interesting and elaborate pertinent presentations that may now be found in scientific literature.

In view of the probability that a large part of the protein molecules in the milk that is consumed, are completely destroyed, and that any formed liberated poisons of disrupted molecules are usually also destroyed in the formation of the diffusible peptones under the action of the acid gastric and the alkaline pancreatic, and other digestice juices; it seems probable that there is a greater chance for the liberation of the protein poisons and their accumulation in a market milk held three days before its consumption, as well as for the transmission to the milk of poisons that may be produced in the cow; than for the production and non-destruction of those poisons in the alimentary tract of the consumer. Nevertheless, it is urged that the fewer protein bacteria that gain entrance to the milk and that are developed in the milk, and introduced into the alimentary canal, the better it will be for the consumer. It seems as if there ought to be enough home produced ferments in the individual's body

to secure the digestion of reasonably adequate amounts of milk without calling on the aid of foreign milk bacteria to provide digestive ferments. Neither is there any need of developing an immunizing power against poisons in the body, whether milk poisons or those of tuberculosis, typhoid, scarlet fever, anthrax, pneumonia, et al, if it is a relatively easy matter to prevent the effects of such poisons through a prohibitive course of action against the production of the poisons and their direct or indirect consumption. Modern civilization increasedly necessitates the consumption of cow's milk and milk products.

The public milk and butter supply is *not* good enough, so long as menacing defects are present or suspected. Protein poisons in food take a higher toll on life than alcohol. Here is one evil needing correction that the Red Cross workers can take up now that the menace of autocracy is well in hand.

94 Prospect Street.

DEATHS BY POISONS IN COOK COUNTY, ILLINOIS, DURING THE PERIOD 1905-1917.*

By WILLIAM D. McNALLY, A.B.,

CHICAGO, ILL.

CHEMIST TO THE CORONER OF COOK COUNTY.

During a period of thirteen years, seventy-four different kinds of poisons were instrumental in causing the death of 2,118 persons. The manner in which the records of the coroner's office were kept prior to 1905 made it very difficult to determine the number of deaths caused by poisons and the nature of the poison. After this date, the records are more complete, but the poison has not always been specifically determined, being designated under the very general heading "Irritant" or "Corrosive" poison. There are also undoubtedly many cases in which drug habit is a contributing factor in causing death, but as this is not always easy to determine, other causes for death are frequently found in the records. Statistics are not available in the coroners' offices of other counties for determining the deaths by poisons and the character of the poison, with the exception of perhaps one or two populous counties. The literature contains references to legal reports, medical, pharmaceutical, and chemical journals, which refer only to special cases, which present points of exceptional scientific interest ,or where the case may have caused undue publicity during the court procedure. Many cases of non-fatal accidental poisonings escape record entirely.

The deaths from carbon monoxide now exceed those from any other poison.' In Cook County our records have shown a steady increase in deaths by such asphyxiation, with the one exception of 1917, when there was a decided drop in the number of cases of suicide. This probably was due to the fact that there were fewer idle people, due to the prosperity brought about by the war conditions. The total number of gas cases for 1916, 501, constitutes nearly 8 per cent. of the entire number of coroner's cases, taking fourth place in numerical order, of different forms of death for the year. Carbon monoxide from domestic gas supply, furnaces, defective stoves, water heaters, smoke of burning buildings claims 4,394 deaths, which is more than double the total of all other poisons combined. In Table No. 1 I have included the total gas asphyxiation cases for the thirteen years from 1905 to 1917 inclusive.

*From the Chemical Laboratory of the Coroner's office, Cook County, Illinois, and the Department of Materia Medica and Toxicology, Rush Medical College.

Table No. 1.—Total Gas Asphyxiation Cases for the Thirteen Years from 1905 to 1918 Inclusive.

Asphyxiation by Gas.	Accidental.	Undetermined.	Industrial.	Water Heaters.	Suicide.	Homicide.	Totals.
1905	59	55	.....	.....	83	7	204
1906	87	36	.....	.....	59	5	187
1907	76	61	.....	.....	74	1	212
1908	85	75	.....	.....	115	3	278
1909	102	81	.....	.....	107	12	302
1910	127	65	10	4	116	7	329
1911	103	66	4	7	115	2	297
1912	110	61	11	10	153	9	354
1913	148	64	.....	1	163	3	379
1914	103	78	3	3	200	5	392
1915	126	93	5	17	242	6	489
1916	160	92	6	6	219	18	501
1917	167	85	10	3	193	12	470
Total	1453	912	49	51	1839	90	4394

In this table, the cases are counted from December 1 to the following December 1, the fiscal year for the coroner's office.

The industrial gas cases and those by water heaters were included with the "accidental" and "undetermined" up to the year 1910.

The popularity of different poisons as an agency for the destruction of life, has varied from time to time. Phenol (carbolic acid) was a very popular poison until the druggist was prohibited by the State Law from selling this poison in a greater strength than 33 1/3 per cent. phenol.

During the thirteen years, statistics show that phenol caused the deaths of 781 people, of which 714 were suicides, 41 accidental, and 26 undetermined. The number of men destroying their lives by this poison was twice that of the number of women during the same period. Table No. 2 shows 545 men, 232 women and four children met death by this agency. The excruciating pains and burns usually caused by phenol would seem to be sufficient to bar its use by people bent upon self-destruction.

Mercuric chloride caused 110 deaths, 87 of which were suicides, 17 accidental, and six undetermined. Seventy-five of these deaths occurred in the last five years. Referring to Table No. 2, it is shown that deaths by mercuric chloride increased each year from 1912 on, the increase being two or three times the number of the years preceding 1912. Impetus was given to this poison by the publicity given to a case of poisoning of a banker in Macon, Ga., who took mercuric chloride tablets by mistake for aspirin. In some cases of this poison, the tablets are claimed to have been taken by mistake for aspirin or lithia tablets, an eror which could be remedied if manufacturers prepared toxitabellæ hydrargyri chloridi corrosivi, as directed in the Ninth Revision of the U. S. Pharmacopœia, or manufactured the tablets in an irregular shape to be dispensed in a porcupine bottle, which would warn the individual that he was handling a dangerous drug.

Cyanides caused 102 deaths, of which 93 were suicides, one murder, three accidental, and five undetermined. Men used this poison more than eight times as often as women. Table No. 2 shows 91

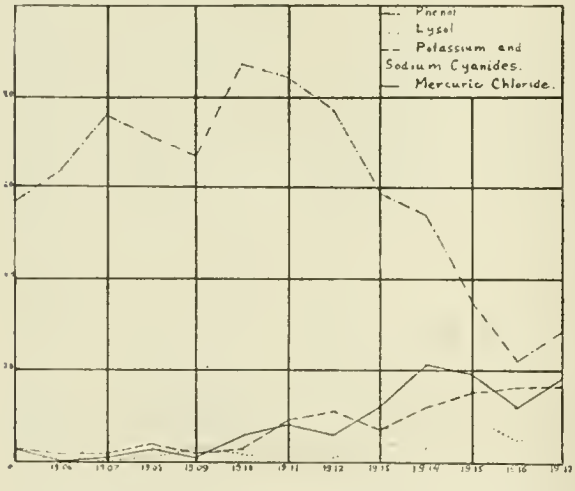
men and 11 women met death by this chemical compound. The verdict rendered at inquests by coroner's jury usually reads "death was due to potassium cyanide," although of over 45 cases investigated, I have found only three cases where the potassium salt had been used. The cyanide of commerce and that dispensed in drug stores is nearly all the sodium salt containing only a small amount of potassium. Prior to 1911 only a few cases of cyanide of potassium were recorded, but the number gradually increased until the maximum number of 16 was reached in 1916. In 1917 cases of cyanide poisoning dropped to half that number.

Our records show that morphine caused 93 deaths, 30 of which were suicides, two murders, 41 accidental, and 20 undetermined, a greater number of men dying from this poison than women. As previously mentioned, other causes for death are frequently found in the records where the drug habit is a contributing factor, the evidence being insufficient for the coroner's jury to determine that morphine was the primary instrument.

Twenty-four of the seventy-four poisons enumerated in Table No. 2 caused only one death each. An unusual case of poisoning was that of sodium borate (borax) mistaken for pancake flour by a cook in a boarding house, which caused the death of one and the serious illness of several people.

The arsenicals used were Paris green, arsenic trioxide, "rough on rats," and Fowler's solution, 5 c.c. of the latter causing the death of a child. Arsenic caused 56 deaths, Paris green 55, rough on rats 38.

Fig. No. 1.



Blyth[2] records during ten years ending December, 1903, that 11,035 died from poisons or poisonous vapors in England and Wales. Deaths from phenol, 1904, outnumbered that of any other poison, with opiate 1655, lead 926, chloroform 862, mineral acid 680, cyanides 535, strychnine 244, arsenic 211. Paris green poisoning is peculiar to the United States, where the use of the poison as a vermicide is very general. In France phosphorus is an agent most frequently employed in criminal poisonings. In Germany and Austria, poisons by the cyanides are exceeded in number only by illuminating gas and mineral acid. In Finland, carbon monoxide, strychnine, and the mineral poisons are the poisons most frequently used. In India arsenic leads all other poisons.

Table No. 3.

	1916.	1915.	1914.	1913.	1912.	Annual Average 1906-10.	Annual Average 1901-05.
Suicide total	10,162	11,216	10,933	9,988	9,656	7,584	4,548
By poison	2,016	2,481	3,000	2,824	2,788	2,281	1,549
By asphyxiation	1,458	1,584	1,419	1,262	1,199	785	365
Accidental or undefined:							
Food	720	639	689	657	573	1,655*	1,412*
Other acute poisonings	1,285	1,280	1,538	1,453	1,348	.....	....

*Food and acute poisonings.

In Table No. 3 the total number of suicides in the registration area[3] shows a gradual increase in the total number of suicides until 1916, when the number decreased 1,054. The number of deaths due to asphyxiation gradually increased, as has already been noted in Cook County.[1] The suicides by poison increased until 1914, when the number reached 3,000, dropping to 2,016 in 1916.

Table No. 4.—Death Rate Per 100,000 Population for Registration Area.

	1916.	1915.	1914.	1913.	1906-10.	1901-05.
Suicide by poison	2.8	3.7	4.5	4.5	4.8	4.7
Suicide by asphyxiation	2.0	2.4	2.2	2.0	1.7	1.1
Accidental or undefined:						
Poisoning by food	1.0	0.9	1.0	1.0	3.5	4.3
Other acute poisonings	1.8	1.9	2.3	2.3		

Table No. 4 shows a gradual decrease in suicides from 4.7 per 100,000 in 1901 to 2.8 per 100,000 in 1916, with a gradual increase in the number of asphyxiations until 1916, when the rate drops 0.4 per 100,000. This decrease in suicides from all causes in the Cook County records has been noticed and attributed, as before mentioned, to the fact that we have fewer idle people due to war conditions.

THE MIND AND ITS ABNORMALITIES.

By B. LEMCHEN, M.D.,
CHICAGO, ILL.
PHYSICIAN, CHICAGO STATE HOSPITAL.

It must be understood that the mind is not an object, and it cannot be treated as such. The mind is a force somewhat like electricity. The force is propagated in the cells of the body, and it follows definite chemical, physical and biological laws which must first be mastered. Without it a clear comprehension of its activities is impossible. While great advances have been made in the science of chemistry, physics, and biology, still our knowledge in these sciences is far from complete; in fact, the known forces are less than the unknown, and especially so with biology, where even the molecular composition and arrangement of the cells during health and disease is not known. Even in the case of dead cells, the composition of some of which has been analyzed, the molecular arrangement has not been mastered up to the present time, and it is self-

evident, when we cannot analyze the cells, that it is still harder to analyze their forces. Still, we cannot afford to wait until the above named sciences are complete and then study the mind, because the burden to society from those with abnormal minds is getting heavier and heavier.

Mind is a biological force, and the force is propagated by all the cells of the body, but only special cells, known as neurons, transmit, store, liberate, and also propagate the force.

The activity of the mind depends on the activity of the entire body, especially, of course, on that of the nervous system. Had our bodies always had the same form, our minds would have been simpler, the forms of insanity fewer, and the individual reactions still fewer. But our ancestors looked quite different from what we do to-day, even not following Darwin to the monkey, for from the remains that are found of man thousands of years back we can judge the difference between the primitive man and the man of to-day. Besides the difference in the figure, the needs were also different from those of the man of to-day. The primitive man was of strong muscular development—long face, strong jaw, and small head. His needs were simple, like food unprepared. His dwellings were caves, and his clothes were skins of animals, or grass, and only such biological forces were stored as were necessary for instinct purposes, but most of them were spent in reflex actions.

How different is the man of to-day—his large head, comparatively small face, weak jaw, and poor muscular development. His needs are great, food must be prepared, dwelling roomy and heated, and clothing better. It is no longer possible to spend most of the biological force in reflex action and save only for instincts, but force has to be saved also for reasoning, judgment, morality, and many other things modern life requires.

What has happened? The cells in the cortex where the biological force is stored have increased in numbers, while the face, jaw, and muscles that have become of less importance have decreased. Now, it must be understood that the biological force we commonly call mind is not the experience of the brain cells themselves nor of a generation, but it represents the experience of all the cells in the body accumulated during the stages of evolution, which represents thousands, if not millions of years.

In the study of comparative anatomy we can hardly fail to see the following facts:

1. The nervous system in lower forms of animals consists of a straight tube with neurons surrounding it, enlarged towards its head with lateral vesicles, from which the hemispheres have developed, and the higher the intelligence of the animal the larger the hemispheres in proportion to the body.

2. The cerebral hemispheres are connected with the entire body, through either the cranial, spinal, or sympathetic nerves. Now let us trace what happens. Waves of light which are physical forces will emanate from an object. It will reach the refracting media of the eyes and an inverted image of the object will be formed on the retina. From there the physical forces will be converted into biological forces, carried to the center of sight, which is supposed to be located in the occipital lobes. There part of the force will be retained for comparison for future times, while part of it will be carried to the associated centers. There again part of the force will be retained for comparison at a future date which we call symbols, while part will be projected back to the periphery and we see the object.

It may be what we see requires action, and part of the force will also be transmitted to the motor neurons, and they will stimulate other cells in action. For instance, when we stop at a place and see a car running into us, we run away. It may even be at a time of great danger that all the force propagated in the sensory organ will be transmitted to the motor neurons, so that a man may see an object, run from it, and when safe may not remember what he ran away from.

What is true of sight is also true of hearing, and of the other senses; and even further, the force started at a sense organ may not only be transmitted direct to the motor neurons, but may take from them force that has already been stored up in some of the neurons, so that not only will the person not remember the incident, but will even forget things that he has known before. The same may occur even in the case of motor neurons, while the neurons themselves may remain normal, and that is why after some accidents people may forget their names or residences and not recognize their relatives, and even be unable to use some muscles, according to the amount of stored forces removed.

We may say that mind is the conversion of physical and chemical forces by the cells of the body into biological force, which sensory neurons transmit to other neurons, where part of the force is retained as symbols, part is projected, and part is transmitted to motor neurons.

Having some conception of the normal mind, we can explain some of the phenomena of the abnormal mind. In organic brain disease we may find that a normal person, after a cerebral insult, may suffer in varying degree from a slight amnesia to profound idiocy, according to the size of the injury to the brain, location, and amount of stored forces the injury has removed. In epileptics, where apparently at intervals the peripheral force is transmitted direct to the motor neurons, some stored force must be removed with each convulsion, and the patient will in time mentally deteriorate; and, as stated before, while the brain where the biological force is stored has developed in stages during the process of evolution, so its decline may also be in stages and a normal person in the involutional period or suffering from chronic intoxications, such as alcoholism, syphilis, autointoxication, etc., where the neurons are getting weaker and the force stored more easily liberated, may decline in morality, affection, emotion, judgment, etc., in any or all spheres. A normal man, after becoming alcoholic, syphilitic, etc., will develop delusions, lose his previous affection for his family, become immoral, depressed, agitated, euphoric, etc.

In some brains, some neurons may either not develop at all, or may not be able to store force and may never possess morality, affection, emotion, judgment, etc. Sometimes the force carried to the associated centers will neither be stored nor transmitted to the motor neurons, but spread out at the associated centers and gradually liberate stored force and project it into the periphery, and the person will

see, hear, smell, etc., imaginary things according to what part of the brain it is projected into, and this is what we commonly call hallucinosis.

What are we to do for the insane? The underlying factor is weakness, and we must see to it that every one develops normally. The rights of the individual do not begin at birth but at the time of the impregnation of the ovum. It is our duty to teach the public the care of the pregnant woman and the growing child, so that it may develop normally, the prevention of infectious diseases, intoxications, and propagation of defectives, and the treatment of the insane scientifically.

Medicolegal Notes.

Liability of Charitable Hospitals.—In an action against the Savannah Hospital certain questions were certified by the Georgia Court of Appeals to the Supreme Court, to which the following answers were given:

The Savannah Hospital, chartered by the General Assembly, is authorized and empowered by its charter to conduct an institution eleemosynary in character for the public benefit. It was not the intention of the Legislature that the business so conducted might be for the pecuniary gain or benefit of its managers, officers, or others. The intention of the Legislature in chartering the corporation is fixed and determined by the acts incorporating it. In a suit against the corporation by a patient for injuries, the charter provisions are controlling, notwithstanding allegations in the petition.

It was asked: "If the Savannah Hospital was chartered as a charitable institution, but, nevertheless, the greater portion thereof was set aside by the officers and superintendent for the treatment of patients who paid for the services they received, would this state of facts render the corporation liable to one who entered the hospital as a patient under an agreement to pay a stated sum for all necessary care, nursing, attention, control, oversight and medical treatment suitable or appropriate to her condition, for any injuries resulting to such patient on account of the negligence, carelessness, or incompetence of the officers and agents of the corporation?" It was answered: "Under circumstances as just enumerated (although the hospital is a charity, and the general rule is that charitable trust funds are not to be depleted by subjection to liability for negligence), the corporation would be liable; but a recovery would be limited to the extent of income derived from treatment of patients who paid for services."

With the exception just stated, an incorporated hospital, primarily maintained as a charitable institution, is held not liable for the negligence of its officers and employees, unless it fails to exercise ordinary care in the selection of competent officers and servants, or fails to exercise ordinary care in retaining such officers and employees.

Where a patient in such an institution is not the recipient of its charity, but is able to pay, and does pay, for the services, and is injured on account of carelessness, negligence, or incompetence of an officer or employee of the institution, the corporation is held liable therefor; but the judgment can only subject funds derived strictly from noncharitable pay patients, and for this purpose the petition need not allege that the corporation failed to exercise ordinary care in the selection of its officers and employees or in retaining them. A judgment so rewarded will not subject funds in trust for charitable purposes, unless the petition alleges that the corporation failed to exercise ordinary care in the selection of its officers and employees, or in retaining them. Morton v. Savannah Hospital, Georgia Supreme Court, 96 S. E. 887.

Selection of Ship Surgeon.—In an action by a passenger against a steamship company for injuries caused by a fall on a slippery bathroom floor, it was alleged that the ship's physician was incompetent in his treatment of the plaintiff and claimed that the vessel was liable. The court thought the evidence did not show that the physician was incompetent. He found the plaintiff suffering from a bruised shoulder. He manipulated it sufficiently to see that the arm moved freely in the socket. He refrained from further manipulations for the reason, as he said, that they would cause pain which was unnecessary, in view of the fact that at the conclusion of the voyage, two or three days later, the plaintiff would have the opportunity to go to his own physician at Honolulu, where an *x*-ray picture could be taken, and the precise nature of the injury could be ascertained; and he advised the plaintiff to have the *x*-ray picture taken immediately upon his arrival in Honolulu. In the meantime, the plaintiff's arm was held in a sling. If there was error in the treatment, it was held a mistake in judgment, and it did not prove incompetency.

Moreover, under Act Aug. 2, 1882, section 5, requiring passenger vessels to carry a competent surgeon or physician, whose services shall be given to passengers needing them, the owner and master discharged their full duty when, in employing a physician, they enquire as to his fitness and obtain recommendations. The Act requires no more than that, in his selection, reasonable care shall be exercised.—The Great Northern, C. C. A., 251 Fed. 826.

Malpractice—Insufficient Evidence of Negligence.—In an action against a surgeon for alleged malpractice, it appeared that the plaintiff was treated by the defendant from November, 1911, until January, 1913. On January 28, 1913, the defendant performed an operation for cataract on the plaintiff's right eye. The operation was not successful, and sight was not restored. As the left eye subsequently became involved from what was apparent sympathetic inflammation, the right eye was removed by the defendant on April 14, 1913. This removal, however, did not allay the trouble with the left eye, and, after further treatment continued for a period of several months, vision in that eye was also lost.

The plaintiff alleged many negligent acts on the part of the defendant, which he said might have produced the blindness. These he summarized in his brief as follows: "Such as general negligence; that the incision on the eyeball of the right eye was within what is called the danger zone; that the defendant did not make a proper diagnosis of the eyes, and did not understand the real condition of the eyes before he operated; that he did not use proper methods in preparing the eye for the operation, and in treating the eyes before and after the operations of January 28 and April 14, 1913."

The evidence introduced by the plaintiff, including that of an eye specialist, failed utterly to substantiate a single one of the many claims set forth in the writ. True, the operation proved unsuccessful, and upon that fact alone the plaintiff seemed to rest his case. But that was held insufficient to establish negligence on the part of the operator. The surgeon cannot insure recovery, and the testimony showed that, with all due care, loss of sight resulted in 5 or 6 per cent. of the cases in operations for cataract, depending in large measure upon the condition of the patient. It was shown here that the plaintiff's trouble was of long standing. His vision had been more or less affected for 40 years.

It was not claimed that the defendant did not possess the ordinary skill of members of his profession in like situations. The law required him to exercise that ordinary skill, and to use reasonable care and diligence in his treatment of the case, and his best judgment in the application of that skill to the case in hand.

The evidence did not show that the defendant failed to measure up to the legal requirement in a single particular, either in the care and treatment prior to the operations, in performing the operations, or in the care and treatment subsequent thereto. The defendant was not called upon to offer any testimony. A jury would not have been justified in drawing from the evidence an inference of legal liability on the part of the defendant, and, therefore, non suit was held properly ordered by the presiding justice.—Curran v. Holt, Maine Supreme Judicial Court, 104 Atl. 579.

Military Medicine.

Acute Respiratory Diseases Among Troops with Especial Reference to Empyema.—In the *Journal of Infectious Diseases* for November, 1918, Captains Lynn S. Neale, Benjamin F. Zimmerman and Searle B. Marlow, M.C., U. S. Army, give the results of a study made by them of acute respiratory diseases among troops. The details are recorded of the incidence of various respiratory conditions, measles, and rubella in their relation to each other and to the more serious conditions, pneumonia and empyema. They summarize as follows: Respiratory infections in 1917 and 1918 occurred among troops in waves, the greatest severity of the diseases being at the height of each wave. Not only were pneumonia and empyema more frequent and severe, but also tonsillitis, pharyngitis, and bronchitis. The most serious infections were characterized by septicemia with empyema, peritonitis, phlegmon, and rarely arthritis, and by pulmonary infection, pneumonia, lobular or lobar in distribution, with consecutive empyema.

While patients who were passing through measles were more severely affected by the streptococcal invasion, the two infections should be regarded as separate even though they were coincident. The empyema and pneumonia were not the result of the measles but of the prevailing severe respiratory infections of that period. The marked freedom from complications of the group of measles treated during the fall and winter of 1917, when general streptococcal infections were absent in camp, and the severe wave of streptococcal pneumonia and empyema, of April, 1918, when measles were on the wane, and which involved for the most part soldiers who had not had measles, are points in support of this view. In a group of 115 consecutive cases of pneumonia and empyema a definite history of an acute antecedent bronchitis, pharyngitis, or tonsillitis was obtained in over 80 per cent. of the cases. In the majority of cases of empyema, a streptococcus has been the causative organism. When grown on blood-agar it has been shown to be usually hemolytic. During the period of prevalence of empyema streptococci were demonstrable in the throats of the majority of healthy soldiers, including fresh recruits, as well as of patients entering the hospitals with respiratory infections. The clinical manifestations of empyema include rapid and profound toxemia, the quick formation in many cases of large amounts of pleural exudate and a marked tendency to pocket formation by old and new adhesions in atypical locations. The mortality was highest (61.5 per cent.) in the cases of empyema following measles, and the lowest (22.7 per cent.) in the cases in which empyema was primary. In empyema complicating pneumonia the mortality was 38.2 per cent.; the mortality of all cases of empyema was 40.5 per cent. At necropsy the outstanding features have been the finding of widespread lesions with a tendency to involve serous membranes, the occurrence of a severe bronchitis in the majority of cases, and a type of bronchopneumonia so distributed as often to resemble closely a lobar process. Early recognition of empyema is important, especially in the acute fulminant type of cases. The diagnosis depends on close attention to clinical progress, frequent observations accurately made and recorded, and proper interpretation of physical signs. Dulness, the sense of resistance on percussion, and the diminution or absence of tactile fremitus are the most reliable signs. The relative incidence of empyema complicating pneumonia was high in one month, 50 per cent. of pneumonia cases developing empyema. Of 830 cases of measles, including rubella, 4.4 per cent. developed pneumonia or empyema; of the group, empyema was the primary condition clinically in 70 per cent. of the cases. The control of such epidemics would appear to depend on the sanitation in barracks as regards ventilation; adequate space and proper separation, especially of those even slightly affected with respiratory disease; on line officers not allowing overheated men to stand inactive in cold winds; on not indiscriminately giving triple typhoid inoculation at the very entrance of the soldier to camp without regard to any respiratory infection he might have at the time; on careful attention to overexertion and exposure of soldiers having mild respiratory disease, and on close attention to the details of equipment to ensure adequate clothing for the unacclimated raw recruit on his arrival.

Death Rate in Camps Increases.—A report by the Surgeon-General of the Army for the six months period ending December 27, 1918, shows that the death rate for the six months rose to 32.15 per thousand per annum from all causes. The rate from influenza and pneumonia was 30.07 per thousand. During demobilization the report states that relatively high mortality and morbidity rates may be expected as only well men are discharged, the sick being retained indefinitely for treatment.

Red Cross Aids Russian Prisoners.—The American Red Cross will begin immediately the work of providing relief for Russian prisoners in Germany, who are said to number 1,500,000. Most of these are in large camps where the sanitary conditions are said to be very bad owing to the lack of soap, disinfectants, and medicines. The Red Cross is sending hospital and disinfecting units, kitchens and canteens with the first relief ship. It is reported that 100,000 Russian prisoners are in hospitals, and that 50,000 more are invalids, chiefly because of consumption which is attributed to the lack of proper food. The Red Cross will supply fats and other foods to supplement the diet furnished the prisoners by Germany. Most of these prisoners have not received any clothing except paper underwear and wooden shoes. The Red Cross will try to supply warm clothing at once.

Care of Shell Shock Cases.—The Army Medical Department, in providing for the treatment of soldiers suffering from so-called "shell shock," will differentiate between the nervous patients and those who are mentally affected, and will treat the two classes of cases in separate institutions. The necessity of this policy was emphasized by the

early experience in England and France. Plans have been formulated by the Surgeon General's office for the proper distribution of these two classes.

Hospital Construction Authorized by War Department.—The War Department has given orders that the following hospital construction work be undertaken at once: At the Walter Reed General Hospital at Washington, D. C., alterations and additions to the receiving ward are to be made and a building is to be constructed for automobile repairs and farm mechanics necessary for physical reconstruction exercises. At Debarkation Hospital No. 51, at Hampton Roads, Va., nurses' quarters, barracks for enlisted men, mess barracks, diet kitchens, alterations in existing barracks, and other changes are to be made. It is estimated that the cost of this work will be $195,000.

Many Wounded Cared for Overseas.—The Senate Committee, in conducting an inquiry into hospital facilities and construction in this country, brought out the information that there are 104,000 wounded men still overseas, may of whom will not be brought home until they have recovered. In the hospitals of this country there are at present about 4,500 vacant beds. The testimony brought out at this inquiry revealed the fact that Assistant Secretary of War Crowell had disapproved the recommendations of the medical authorities to build a $3,250,000 military hospital at Chicago.

War Wounds Leave Many Blind.—The number of totally blinded victims of the war among the Allied Forces has now been calculated as 7,000. According to estimates twenty-five or thirty per cent. will have to be added to this figure from among the patients now undergoing treatment. The total of those who lost one eye amounts to between 30,000 and 40,000.

Hospital for Czecho-Slovaks.—The American Red Cross has put in operation a completely equipped modern military hospital for sick and wounded members of the Czecho-Slovak forces, at Cognac, France. The hospital was equipped under the direction of Dr. Howard Lewis of the American Red Cross and is a model of the small military type. The doctor in charge and the personnel of the hospital are all members of the Czecho-Slovak army.

Fire in Naval Hospital.—The galley attached to the Pelham Bay Naval Training Station was almost destroyed by fire recently and two of the hospital buildings were damaged. It was found necessary to remove many of the patients from the hospital, which for a time was threatened by the blaze. Discipline prevailed, however, and there was little excitement. The damage is estimated at $15,000.

Auto Trips for Wounded Soldiers and Sailors.—Sight seeing excursions for wounded men in the hospitals of New York have been inaugurated. The New York War Camp Community Service buses took the first party of men from the Debarkation Hospital at Sixth Avenue and Eighteenth Street, the old Greenhut Building. The trips cover points that are usually of interest to sight-seeing visitors in the city.

Surgeon General Merritte W. Ireland and Col. Walter E. Bradley have been presented with Distinguished Service Crosses by General Pershing in recognition of their devoted services to the country during the war.

Brig.-Gen. William S. Thayer of Baltimore has returned to this country and will resume his work as professor of clinical medicine at Johns Hopkins University.

Recreation at Military Hospitals.—The Surgeon General's office and the American Red Cross have co-operated in formulating plans for providing recreational activities in forty reconstruction hospitals in the United States. Dr. Elbert K. Fretwell of Columbia University has charge of the undertaking and has started on a tour of the hospitals on the Atlantic Seaboard where wounded soldiers are being cared for. The organization now engaged in welfare work among soldiers will be utilized in furthering this plan, the aim of which is to provide indoor games, athletics, books, gardening materials, and everything calculated to improve the mental and physical condition of the men under treatment.

Military Hospitals Will Help Relatives Find Soldiers.—The War Department has devised a plan which will soon be put into operation to assist relatives to get in touch with wounded soldiers admitted to military hospitals. Military hospitals will be required to send cards reporting immediately to the nearest of kin when a soldier is admitted, what his wound or ailment is, and what his general condition. Transfers of men from one hospital to another will also be reported.

Aid Asked for American Military Hospital No. 1.—Announcement is made through the Atlantic Division of the American Red Cross that American Military Hospital No. 1 will be needed throughout the year 1919 to care for sick and wounded soldiers and that many beds should be endowed. The President General and Chairman of the War Relief have been officially informed that re-endowment may be upon a basis of six months and $50 a month thereafter for such a time as the beds may be needed.

Deaths in the Service.—Lieut. Clyde Lorenzo Carey, M. C., U. S. Army, of Elmira, N. Y., a graduate of the University of Buffalo, in 1910, died of pneumonia at his home, on January 6, aged 34 years. He was president of the Chemung County Medical Society, and a member of the Elmira Academy of Medicine.

Major Robert Lord Hull, M. C., U. S. Army, of Oklahoma City, a graduate of Jefferson Medical College, Philadelphia, in 1902, died from pneumonia following influenza, at the Letterman Generla Hospital, Presidio, San Francisco, on January 5, aged 43 years. He was associate professor of orthopedic surgery in the University of Oklahoma, chief surgeon of the Emergency and St. Anthony Hospitals, Oklahoma City, and head of the orthopedic department of the Letterman General Hospital.

Lieut. Samuel Leo Oren, M. C., U. S. Army, of Lewistown, Ill., a graduate of Barnes Medical College, St. Louis, in 1899, aged 39 years, died in France on October 9, from nervous collapse, presumably following ambulant typhoid fever.

Capt. Herbert Martin Howes, M. C., U. S.

Army, of Portland, Me., a graduate of the Bowdoin Medical School, in 1917, and assistant professor of pathology in his alma mater, who was honorably discharged from the Medical Corps of the army on December 21, died from pneumonia following influenza, at his home, on January 5, aged 28 years.

LIEUT. HERBERT LEER MCNIEL, M. C., U. S. Army, of Houston, Texas, a graduate of Johns Hopkins University, in 1911, aged 32 years, died while on duty with the American Expeditionary Forces in France, at Camp Hospital No. 30, on November 30, from bronchopneumonia.

CAPT. CHARLES HENRY WEINTZ, M. C., U. S. Army, of Cincinanti, a graduate of Miami Medical College, in 1909, died from pneumonia at Camp Sherman, Chillicothe, Ohio, on October 14, aged 33 years. He was assistant chief of the nose and throat department of the base hospital.

LIEUT.-COL. CARL EDWARD HOLMBERG, M. C., U. S. Army, of Whipple Barracks, Ariz., a graduate of Jefferson Medical College, Philadelphia, in 1908, commanding officer of United States Army General Hospital No. 20, Whipple Barracks, Ariz., died in that institution from bronchopneumonia, on January 1, aged 39 years.

LIEUT. JOSEPH ALPHONSE FURLONG, M. C., U. S. Army, of Spring View, Neb., a graduate of St. Louis University, in 1912, aged 29 years, on duty with the American Expeditionary Forces in France, lost his life when the steamship *Leinster*, on which he was returning to this country, was torpedoed off the coast of Ireland on October 10.

LIEUT. JEROME MCKAIG LEONARD, M. C., U. S. Army, of Douglas, Ariz., a graduate of Hahnemann Medical College, Chicago, in 1906, aged 34 years, was killed in action while on duty with the American Expeditionary Forces in France, on November 8.

LIEUT. DAVID NEEPER RICHARDS, M. C., U. S. Army, of Germantown, Md., a graduate of Johns Hopkins University, in 1915, aged 28 years, on duty with Evacuation Hospital No. 49, American Expeditionary Forces in France since June, 1918, died of bronchial pneumonia following influenza, at Camp Merritt, N. J., on October 12.

CAPT. JOHN EDWIN RAY, JR., M. C., U. S. Army, of Raleigh, N. C., a graduate of Cornell University Medical School, New York, in 1912, aged 31 years, died of wounds received in action in Bellicourt, while on duty with the American Expeditionary Forces in France, on October 5.

LIEUT. JAMES FRANCIS GORMAN, U. S. N. R. F., of Manchester, Conn., a graduate of Georgetown University, Washington, D. C., who had been on duty at the Brooklyn Navy Yard, died at his home in Manchester, from pneumonia following influenza, on December 28, aged 34 years.

LIEUT. STANLEY LEE CASSELL, M. C., U. S. Army, of Sweet Grass, Mont., a graduate of the University of Illinois, Chicago, in 1914, aged 28 years, was killed while on duty with the American Expeditionary Forces in France, on November 4, at Earle Fontaine, by a shell explosion.

LIEUT. ROBERT ELDRIDGE HEARN, M. C., U. S. Army, of Mabank, Texas, a graduate of the University of Louisville, Ky., in 1904, on duty at Camp Funston, Leon Springs, Texas, died from bronchopnuemonia on October 18, aged 39 years.

LIEUT. CASPER JOSEPH MIDDLEKAUFF, M. C., U. S. Army, of Hayes, Kan., a graduate of Jefferson Medical College, in 1917, aged 31 years, died from pneumonia while on duty with the American Expeditionary Forces in France, on October 8.

LIEUT. SAMUEL DANA HENDERSON, M. C., U. S. Army, of Lansford, N. D., a graduate of Tulane University, New Orleans, in 1916, died from pneumonia following influenza, at Camp Greenleaf, Ga., on October 19, aged 30 years.

LIEUT. BURGESS ALLEN GIBSON, M. C., U. S. Army, of Washingtonville, Pa., aged 30 years, died from the effects of wounds received in action on November 3. He was a graduate of Jefferson Medical College, Philadelphia, in 1913.

LIEUT. CLYDE EVERATT SHEDD, M. C., U. S. Army, of San Francisco, Cal., a graduate of the Oakland (Cal.) College of Medicine and Surgery, in 1917, aged 25 years, was killed in action in France, November 4.

LIEUT. JULIUS LEWIS SHRYER, M. C., U. S. Army, of Durant, Iowa, a graduate of the Chicago College of Medicine and Surgery, in 1917, died from bronchial pneumonia, in France, on November 4, aged 29 years.

LIEUT. EARLE WILLIAM GILROY, M. C., U. S. Army, of Minneapolis, a graduate of Rush Medical College, in 1916, and head of the department of pathology at the base hospital at Camp Wheeler, Macon, Ga., died in Minneapolis, on December 30, of pneumonia following influenza, aged 25 years.

LIEUT. CARL DINSMORE GRAY, M. C., U. S. Army, of Portland, Me., a graduate of Bowdoin Medical School, who had been honorably discharged from the service, died while en route to his home in Portland, of complications following influenza, on December 19, aged 32 years.

LIEUT. GEORGE BUOL, M. C., U. S. Army, of Ravenna, Neb., a graduate of the University of Nebraska, Omaha, in 1910, aged 32 years, on duty at Camp Funston, Kan., was instantly killed on December 21, when his automobile was struck by a Burlington train at a grade crossing at Streetwater, Neb.

CAPT. PAUL LEE COCKE, M. C., U. S. Army, of Birmingham, Ala., a graduate of the University of Virginia, Charlottesville, in 1899, on duty with the American Expeditionary Forces in France, died in Paris, July 27, from concussion of the brain following an automobile accident, at the age of 43 years.

LIEUT. WILLIAM CLEVELAND REESE, M. C., U. S. Army, of Wilkes-Barre, Pa., a graduate of the University of Pennsylvania, Philadelphia, in 1910, a member of the staff of the Wilkes-Barre City Hospital, died from pneumonia, following influenza, on October 20, aged 34 years.

LIEUT. CHARLES VERMILYEA, M. C., U. S. Army, of Poughkeepsie, N. Y., a graduate of the University of Syracuse, N. Y., in 1912, aged 31 years, is reported to have died in the service, in France, several months ago. Before enlisting in the army he was assistant physician in the Hudson River State Hospital.

CAPT. THEODORE LEGRANDE BURNETT, M. C., U. S. Army, of Louisville, Ky., died of pneumonia following influenza, while on duty at Camp Shelby, Hattiesburg, Miss., on November 5, aged 28 years.

FLEXION OF THE GREAT TOE; A SIGN OF LESIONS OF THE SCIATIC NERVE AND ITS BRANCHES.

THE sign of the great toe (Villaret's sign) is dependent upon an increase of the neuromuscular reflectivity which can be readily detected in cases of lesion of the sciatic nerve and its branches. Percussion of the tendo Achillis, when there is some pathological disturbance of the sciatic, will reveal a plantar flexion of the great toe, while at the same time the plantar flexion of the foot will be weakened or absent. Under normal circumstances percussion of the tendo Achillis produces nothing of the kind, the great toe does not change its position while the foot becomes flexed. It may, however, happen, although very infrequently, that a slight flexion of the great toe occurs, and in order that this sign shall have a diagnostic value there must be, firstly, a marked flexion quite distinct from that obtained on the normal side and, secondly, a simultaneous exaggeration of the neuromuscular reflectivity.

The technique to be followed for obtaining these clinical evidences is as follows: To detect the phenomenon of flexion of the great toe the leg is slightly flexed with the thigh in abduction, the patient lying down. The phenomenon will acquire greater distinctness if percussion is carried out along the internal border of the tendo Achillis, on the posterior lip of the retromalleolar gutter, in other words, over the internal border of the flexor longus pollicis, which still possesses muscular fibers at this level and passes beyond the internal border of the tendo Achillis. It is to be remarked that in case of extreme hypotonia of the lower limb, the jump imparted to the foot by the hammer percussing the tendo Achillis may be mechanically transmitted to the other toes, imparting a kind of passive nutation proportional to their mass. In these circumstances flexion of the great toe may appear to have occurred, but in reality quite easily distinguished from active muscular movement, which is slower and more ample. The tendo Achillis reflex is to be sought for with the patient kneeling on the edge of the bed or a chair, and all that is required is to percuss the tendon and compare the resulting reflex with the opposite side. Jumentié has resorted to the graphic method and has been able to note that, according to the degree of the lesion, there is either an exaggeration of the neuromuscular reflectivity of the gastrocnemius and the normal reflex of the tendo Achillis, or a weakening of the latter and an exaggeration of the neuromuscular reflectivity, or absence of the reflex with exaggeration, attenuation, or even absence of the neuromuscular reflectivity.

The exaggeration of the neuromuscular reflectivity of the gastrocnemius and the muscles innervated by a pathologically involved nerve is readily understood. Neuromuscular contractility is independent of bone, tendon, or cutaneous contractility to such an extent that it is quite proper to speak of neuromuscular reflectivity, because it is a true reflex. Therefore, it is not surprising that for the same muscle a decrease of the tendinous and neuromuscular reflectivity may coexist. For that matter, this is quite normal in peripheral paralyses, be they of organic or other nature. The phenomenon of the reflex of the great toe is intimately united to neuromuscular reflectivity and this becomes more evident if, instead of percussing the tendo Achillis, this is carried out along its internal border, because by so doing the internal border of the flexor longus pollicis is percussed. This sign is, consequently, a neuromuscular reflex. The flexor longus pollicis and the sural triceps receive the same innervation, so that their neuromuscular reflectivity undergoes necessarily the same variations in identical circumstances.

Now, how does it happen that when in the normal state percussion in the internal retromalleolar gutter which is over both the flexor longus pollicis and the internal border of the gastrocnemius, there is a plantar reflex and not of the great toe? And why in the normal state is there not rather a digression between the plantar flexion of the foot and that of the great toe? In answer to this question one must necessarily admit that in the variation of its intensity it is the neuromuscular reflectivity of the small muscles which especially increases. In the case of percussion of the tendo Achillis the tendinous reflectivity is explored, which in case of lesion of the sciatic is diminished or absent according to the extent of morbid change in the nerve and by *contre-coup*, the neuromuscular reflectivity of the flexor longus pollicis is explored and which, on the contrary, is increased. A practical conclusion imposes itself, namely, in searching for the neuromuscular reflectivity of the great toe, percussion should be carried out high up in the retromalleolar gutter in order to percuss the muscle and not its tendon.

THE CAUSATIVE FACTORS OF HEMATOCELE OF THE THYROID GLAND.

CYSTIC adenoma of the thyroid, by its presence in the gland, produces certain perturbations which are the direct causes of hematocele in goiter. Under the influence of the growth the surrounding struc-

tures become congested, resulting in a series of intraglandular hemorrhages, these being followed by foci of sclerosis, which form a more or less thick shell around the cyst. The same phenomenon occurs on the lining membrane of the cyst with intense proliferation of the epithelial cells, and from this process papillary growths develop, composed merely of a simple endothelial covering into which neighboring embryonal capillaries penetrate. The presence of the pericystic fibrous zone still more increases the tension of these new-formed vessels, which, on account of their thin walls, easily rupture. They are also dilated, and this decreases their resistance and explains why the hemorrhage may be considerable in amount. When one of these capillaries ruptures the blood mixes with the colloid fluid contained in the cyst and then fibrinous clots, variously colored by the pigment of the altered red blood corpuscles, are deposited, carrying cell débris along with them. If the hemorrhage is considerable, the blood will distend the cyst and the exogenous capillaries, being flattened, rupture.

A certain number of thyroid hematoceles appearing during labor have been recorded, and are supposed to be caused by congestion of the gland, followed by vascular rupture from dilatation and softening of the vessel walls. But these congestive phenomena of pregnancy do not come under the head of the process under consideration. No matter what causative factor be admitted, it nevertheless remains a fact that there is a marked dilatation of the perithyroid venous system, and this return circulation being interfered with will react on the pericystic capillaries. At a given moment the equilibrium between the pressure of the intracystic fluid and the capillaries ceases, from which results rupture of the neoformed capillaries in the intracystic vegetations and hemorrhage into the thyroid pocket. This process is quite similar to those lesser hemorrhages encountered during simple thyroid congestion involving the entire gland, and it is only the presence of the cyst which gives to this benign accident quite another physiognomy.

As to intrinsic causes, it has been admitted by some that a decrease of the intracystic pressure may occur from certain chemical changes arising in the fluid content, thus resulting in hemorrhage within the cyst. But this theory is unsatisfactory and has never been confirmed by either a physical or a histological examination. There are two hypotheses that are tenable if one admits *a priori* that the tension of the intracystic fluid has remained the same while the pressure in the neighboring capillaries has increased, causing their rupture, or there exists an irritative process of the lining membrane of the cyst, in which the intracystic outgrowths participate and become the direct factors, perhaps the only ones, of the hematocele.

Therefore, the process may be summed up as follows: The fibrinous clot extends over the entire inner lining of the cyst, imprisoning the leucocytes, while at the same time contracting adhesions with the surrounding parenchyma, which sends off angioplastic cells to it. These are quickly transformed into blood vessels. The fragility of the vascular walls explains their rupture, but the cruoric deposit becomes a new fibrinous deposit from which new membranes and vessels result, likewise renewed hemorrhage, so that a thyroid hematocele is absolutely comparable to a pelvic hematocele, but it differs from the latter in that its purulent transformation is much more frequent.

INFLUENZA TRANSMITTED BY INDIRECT CONTACT.

IT is agreed without demur that influenza is a disease which is communicated with great facility, and it is believed to be spread chiefly through discharges from the nose and throat. While it is generallly believed that direct contact is one of the most important factors in the dissemination of influenza, there is small room for doubt that indirect contact plays a part in its spread. The results of an investigation as to the incidence of influenza carried out by Col. Charles Lynch and Lieut. Col. James G. Cumming, published in the *American Journal of Public Health* for January, 1919, appear to show that the major route of transmission of influenza infection is by indirect contact. The investigations covered a total of 66,000 troops and the findings were of very considerable value. It seems to have been demonstrated that mess kit wash water contaminated by mouth organisms was responsible for a large proportion of the cases of influenza which occurred among these men.

The contamination of the water by mouth organisms took place by two routes of travel, from the mouth to mess equipment, thence to wash water, also from the nose and mouth to the hands and thence to wash water. It was, according to these investigations, the hands which were kept in a constant state of contamination by tepid dish water. As it is the invariable custom for the hands to visit noses and mouths frequently, the conclusion was reached that warm dishwater is the most intimate and frequent point of contact among troops for the exchange of mouth organisms. Figures as to mortality rates gathered from the various camps in which the 66,000 men were stationed, showed that the incidence of and death rate from pneumonia coincided with the washing of the mess equipment in unsterilized water. That is, deaths from pneumonia were few in the battalion in which the mess equipment was washed in boiling water and high in the battalion in which warm water was used for this purpose. The ratio of influenza in these two organizations was 1 to 12, and the incidence paralleled closely the ratio of deaths in the two organizations. It may be further noted that the members of the battalion in which warm water was employed were physically unfit, while that in which boiling water was used was composed of hardy, vigorous men.

The authors argue that not only was influenza

caused indirectly by contaminated dish water, but that streptococcal pneumonia was largely transmitted in the same manner. It was found that in civil life only 5 per cent. of average throats harbor hemolytic streptococci and that among troops 35 per cent. of measles cases harbor these organisms. Cols. Lynch and Cumming take the stand that if warm mess water was, as they have shown, responsible for approximately 80 per cent. of the cases of influenza, the conclusion is justified from the fact that they succeeded in isolating streptococci almost invariably from the hands of streptococcus carriers, that the epidemic of streptococcus pneumonia was due to the facility of transmission by means of the mess kit washing water.

From these investigations it may be fairly deduced that the hands and eating utensils play a prominent rôle in the transmission of influenza and streptococcal pneumonia and probably of many infectious diseases, and that infection by indirect contact is of great consequence. If this be so, and the evidence appears to point strongly in this direction, the advice given by the authors should be closely followed. They insist that the essentials of prevention are clean hands, disinfected eating utensils, the avoidance of intermediate object conveyors handled by many persons, the frequent cleansing of such conveyors, the keeping the hands away from the mouth and nose, and the elimination of sick persons from the kitchen.

PARASPECIFIC SEROTHERAPY IN OPHTHALMIC PRACTICE.

THE vast amount of work done during the past few years on serotherapy has shown beyond a doubt that antidiphtheritic serum is a very great aid in ophthalmology and that this paraspecific serotherapy powerfully excites the defensive powers of the organism, increasing the phagocytic properties of the leucocytes. It is also true that paraspecific serotherapy by mouth may produce the same effects as when the serum is given by injection; it does away with the pain, causes absorption of the exudates, and checks the infectious process. But paraspecific serotherapy by mouth is not infallible. It is a powerful aid to the defensive activity of the tissues and a tonic which helps the organism to resist the progress of infection, but when the latter is too far advanced or too virulent nothing can control it, and this is a point which must never be overlooked.

In pseudomembranous conjunctivitis which may have such a variable etiology (gonococcus, pneumococcus, staphylococcus, etc.), serotherapy by mouth has a favorable action on the pathological process. If the corneal lesions are advanced the necrotic process may be checked, but if the cornea is perforated, serotherapy will act only indirectly on the lesions by reestablishing the normal nutrition in the tissues and preventing the occurrence of leucoma.

In infectious ulcers of the cornea paraspecific serotherapy acts as a general stimulant and a very great aid to the local treatment of the lesion. The antidiphtheritic serum must be given, in a potion, in the dose of 10 c.c. (2,500 antitoxic units) in twenty-four hours. The action of the serum is made manifest by a very marked state of euphoria, allowing the patient to sleep the entire night after the first dose of serum. The following day the pain will be greatly lessened and the patient can open the eye and better support light. The resulting leucoma will be less extensive, much more transparent, and vision will be better than with any other treatment.

Although many have denied the good effects of serotherapy by mouth in lesions of the cornea, there appears to be a unanimous accord in its favor in cases of iritis with hypopyon and the very violent and painful plastic iritides. There is no better soil on which to study the action of paraspecific serotherapy by mouth than in infections of the iris. The process can be seen but cannot be acted upon directly with topics; atropine and dionine exercise an action on the iris. But when these two therapeutic agents have remained without action on the pupil and without influencing the pain for several days, the action of the serum given per os becomes manifest, because in a few hours after seric medication, usually after the sixth or seventh spoonful of the potion, the pain commences to diminish and finally completely subsides. The following day the eye is less red and tumefied and more mobile in the orbit. The pupil gives way slowly to the action of atropine, the exudates in the anterior chamber are rapidly absorbed and in four or five days recovery is apparent and it only remains to attack the primary etiological factor of the process—whatever that may be—mercury or arsenic in syphilis, the salicylates in rheumatism, antigonococcic vaccines if a gonorrheal infection is present.

But where paraspecific serotherapy is at its acme of therapeutic value is in infection following the extraction of cataract. Generally speaking, if the infection is dealt with at its beginning, within four to eight days, the prognosis becomes more favorable, while at the end of a month the vision will be about the same as that obtained in a normal operation. In serious infection involving the vitreous humor, serotherapy will be of no more use than any other medication in checking the infectious process. But in general no treatment employed up to date has given such rapid and constant results, involving no risk whatsoever.

RETURNED SOLDIERS AND COMMUNICABLE DISEASES.

THERE is reason to fear that certain communicable diseases may be introduced into this country by returned soldiers. These are especially those which have been shown to be spread by lice or other insects, as for example, typhus fever and plague. Also there is certain to be some of the many thousands of returned soldiers who are carriers of disease. The Public Health Service, however, is awake to the menace and is putting measures into effect

to meet the situation. In Public Health Reports for December 6, 1918, it is stated that explicit instructions have been issued to all quarantine officers, urging the most careful examination, including laboratory tests, of all units of the returning armies liable to be carriers of exotic epidemic communicable diseases. Moreover, officers of the Public Health Service trained in quarantine procedure either have been sent to various ports of Europe or will be sent as the occasion may arise. They will there supervise the enforcement of the United States quarantine regulations applicable at foreign ports against ships and passengers destined for ports of the United States. It is anticipated that compliance with the quarantine regulations, as bearing on returning troops, will be effected by the cooperation of the United States military authorities in the examination, delousing, and disinfection, when necessary, of the troops prior to embarkation. While there appears to be little danger of the introduction of cholera from American soldiers now in France and Germany, there may be danger of the introduction of this disease from the Russian front, where conditions are still very disturbed and where cholera is now known to be more or less prevalent. There is, however, greater reason to fear that trench fever or typhus may be brought in by infected lice on the bodies of returned soldiers. Therefore, it imparts confidence to learn that the Public Health Service is doing its share to prevent the introduction of foreign communicable diseases into America. Precautions of a similar nature are being taken to prevent the spread of disease by soldiers discharged from training camps.

Clinostatic Bradycardia.

The phenomenon of marked slowing of the pulse rate in paroxysmal tachycardia, which supervenes immediately upon lying down, may not be rare, but Vincent has isolated an entire syndrome which he terms clinostatic bradycardia (*Journal de médecine et de chirurgie pratiques*, November 10). This author has noted the phenomenon often in sound adolescents of dull intelligence. One element is an acrocyanosis which in winter aggravates the natural violaceous hue due to exposure. This appears along with the bradycardia when the subject lies down. There is noted a drop of the blood pressure to somewhere between 110 and 140. The corresponding fall in the pulse rate is from normal limits to 58, 52, or even 40. No tachycardia is mentioned in this connection. When the subject first stands up again the pulse quickens, but the pressure soon falls 20 or 30 more millimeters. This triad of bradycardia, lessened blood pressure, and acrocyanosis appears to have a sexual significance, for in young women it may disappear after marriage and childbirth. The author instituted a research for an endocrinic component which included an examination of the glands and treatment tests. The thyroid, according to the case, showed either enlargement or atrophy. A combination of thyroid extract with iodides yielded remarkable improvement. As these patients are very subject to chilblains, the improvement in the latter was often striking. In a few days the pulse on standing increased only the normal amount under the circumstances.

Antihrax Cured by Neosalvarsan.

The idea of anthrax which obtains to-day is that the nonseptic forms are amenable to various kinds of treatment, some of which may be quite simple, while septic anthrax, like all sepsis, is very refractory to any plan of treatment. The alleged remarkable cures which find their way into literature are usually of localized forms, which, while they may present a marked constitutional reaction, are seldom septic in the true sense of the term. Much confusion is associated with the management of the disease on this account. Whether serum treatment has ever actually prevailed over true bacteriemia is still open to doubt. In the *Correspondenz-Blatt für Schweizer Aerzte* for November 9, 1918, Gsell refers to the use of salvarsan in this affection. In the original case of Becker the general condition was bad, but the blood remained sterile, and the same was the case with others related. Salvarsan was successful in cases of this type, but made an inglorious failure in others in which bacteriemia was present. Only in the laboratory did this remedy cure septic cases, the bacilli dying in the blood within a short time, as shown by failure to develop blood cultures after treatment. The author's case was not of especial severity, and was not septic at any time, but yielded so promptly to intravenous injections of neosalvarsan that the result deserved to be called favorable.

News of the Week.

Influenza Epidemic Continues in the United States.—Although the influenza epidemic has about completed its sixteenth week, and the number of cases reported is not much above the low level reached in its tenth week, there is no definite sign of a letup. The most recent figures compiled by the United States Public Health Service estimate the number of deaths from influenza in the United States at 145,512. This death rate is 50 per cent. more than the combined total of the epidemics of 1889 and 1891. In New York City for the week ended January 25 the rate was considerably higher than for some weeks, the daily average of new cases reported running between 500 and 600. In view of these reports, Health Commissioner Copeland has requested the police again to distribute circulars containing suggestions as to how a recurrence of the epidemic might be avoided.

Influenza Toll in Jamaica.—A special cable from Kingston, Jamaica, to the *New York Times* reports that Government statistics show an increase of 160 per cent. in deaths from October to December, the period during which influenza was epidemic. During the last quarter of 1917 there were 5,699 deaths, and during the corresponding period of 1918 there were 13,373 deaths. It is estimated that more than one-third of the population was affected by the epidemic.

Influenza in India.—Influenza and famine conditions are said to be causing a death rate seven times as great as during the plague last spring in certain sections of India, according to advices received by the Board of Foreign Missions of the Presbyterian Church.

Bubonic Plague in Argentina.—A report from

Buenos Aires states that the Government of that country is sending a commission to the Province of Jujuy for the purpose of fighting the epidemic of bubonic plague, which is reported to be serious. The Santiago Dispensary reports 605 cases of typhus fever and 13 deaths.

Smallpox in Dresden.—A sudden and violent outbreak of smallpox has broken out at Dresden, according to a telegram from Constance. Official reports show 125 cases of the disease, which is said to have been introduced from Bohemia, where the disease has been raging for several weeks.

Cholera in Hamburg.—A telegram received in London from an Amsterdam correspondent states that an outbreak of cholera has occurred in Hamburg. Seventy fatal cases have been reported.

War Increases Mental Disease.—Figures compiled by the New York State Hospital Commission show that 3,995 more patients have been admitted to the State hospitals during the forty-four months since war was declared than for the similar period of time prior to the beginning of hostilities, the admissions prior to the war being 29,316, as against 33,311 afterward. The State hospitals are actually housing 6,500 more patients than they were built to accommodate. The State Commission on the Feebleminded has mapped out a program for the relief of this condition, which has been presented to Governor Smith.

Physicians Needed in Rural Sections.—Many rural communities in New York State are absolutely without a physician according to letters that are daily being received at the State Department of Health. With many country roads becoming practically impassable, the situation in many cases is very serious, as neighboring towns can no longer be depended on for medical assistance in emergencies. In order to aid these communities the State Department of Health has placed advertisements in some of the medical journals for physicians who desire to locate in rural communities. A large number of replies have already been received from qualified physicians, and it is believed that the situation will soon be relieved.

Annual Meeting of United Hospital Fund.—At the annual meeting on January 13, of this organization which divides its funds among forty hospitals of New York City, it was announced that for the fiscal year just ended the receipts were $183,778, a gain of 36 per cent. over last year. In order to meet the increased cost of maintenance and the greater demand for free service the fund plans to raise $250,000 during the present year. Dr. George E. Brewer, W. V. S. Thorne, and James McVickar Breed were elected trustees of the Fund.

Charitable Bequests.—By the will of the late Mary H. Wood of Morristown, Pa., bequests are made as follows: $10,000 each to the Philadelphia Home for Incurables, Woman's Medical College of Pennsylvania, Woman's Hospital, and the Charity Hospital at Norristown.

By the will of the late Sarah R. Watson of Philadelphia, the sum of $1,000 is bequeathed to the Germantown Hospital and Dispensary.

By the will of the late Abbie E. Sinnott of Philadelphia, bequests are made as follows: St. Vincent's Home and Maternity Hospital, $11,000; Philadelphia Home for Incurables, $4,000.

Philadelphia Psychiatric Society.—At the annual meeting, held January 10, Dr. Charles S. Potts delivered the president's address, which was entitled "A Study of the Effects of Alcohol from a New Standpoint." He contended that there had been a good deal of hysteria and hypocrisy in the crusade against alcohol. He pointed out that the use of alcohol in some form dates from the earliest times recorded, and that the status of civilization and progress was not less high among those peoples accustomed to its use than among those who abstained by reason of religious inhibition. He named a number of the great men in history who were in the habit of using alcohol.

Guard Port of New York Against Smallpox.—A statement recently issued by Health Commissioner Royal S. Copeland calls attention to the fact that smallpox of a virulent type is raging in certain sections of Italy, and to guard against the disease being brought into New York the strictest precautions must be observed. The closest possible inspection is made of every incoming vessel from an Italian port. Every passenger from Italy will be vaccinated if the time since the departure of a ship from an infected port has been less than sixteen days. No passenger will be permitted to land until that time has elapsed. The New York Health Department is given the name and destination of every person who enters the United States. If he tarries in New York City he will be kept under the observation of the officials of the Health Department until all possible danger has passed. If he does not remain in the city the health officials of the place to which he is going are notified. The health commissioner announces that there is no occasion for alarm at the present time, the purpose of the statement being to avoid disquieting rumors and to fortify the public against groundless fears.

Milk Strike Increased Infant Mortality.—According to the statistics of the New York Department of Health, introduced at the John Doe milk inquiry, the recent milk strike has been responsible for a sudden and marked rise in the infant mortality rates of this city. The deaths of children under one year of age per 1,000 births during December were as follows: Week ended December 7, 109; week ended December 14, 210; week ended December 21, 204; week ended December 28, 175. The milk strike started on January 1 and ended January 18, and during this period the deaths of children under one year per 1,000 births were as follows: January 4, 243; week ended January 11, 221; week ended January 18, 277. There seems to be no other factor excepting the lack of milk to account for this increased death rate, as the weather during this period was mild. In the discussion of the milk problem, Irwin E. Jennings, formerly secretary of a large distributing company, who has made several investigations of the city's milk problem, suggests that if all other measures fail it may be necessary to have the State or municipality assume control of the distribution machinery, and as a last resort take over the direction of both the production and the distribution of milk.

Health Bill Endorsed.—The Council of Organizations, representing 400 bodies in New York, met

on January 24 to discuss ways to meet the present health emergency. It was the sense of the meeting that it is highly important that matters pertaining to health be brought to the attention of Congress for proper legislative action, especially infant hygiene. The speakers approved the Rankin-Robinson bill now before Congress, the aim of which is to preserve all the bureaus of industrial hygiene. At this meeting resolutions were passed protesting against Health Commissioner Royal S. Copeland's plan to remove the Division of Industrial Hygiene from the Bureau of Preventable Diseases.

Health Commissioner Defends Changes in Administration.—On the invitation of Health Commissioner Royal S. Copeland, representatives of labor and civic organizations of New York City met in the Department of Health Building on January 24 to discuss the advisability of the removal of the Division of Industrial Hygiene from the Bureau of Preventable Diseases, of which Dr. Louis I. Harris is director, and placing it under the direct care of the Health Commissioner. Commissioner Copeland explained that he had made the change because the work of the Bureau of Preventable Diseases was sufficiently onerous without the additional labor imposed by the Division of Industrial Hygiene, and that he believed the change would insure better protection to the public from communicable diseases. This change in administration, he said, would not leave the health of industrial workers unprotected. He asked that criticism be deferred until his plan had had a trial. Rabbi Sidney E. Goldstein suggested in a recent sermon that the citizens request the Committee on Public Health of the New York Academy of Medicine and invited experts on public health and social welfare to make an investigation. In reply to this suggestion, Dr. Copeland is reported as saying that if he had to submit his problems to a committee named by Rabbi Goldstein he would "quit right now." On the day following this conference Dr. Copeland appointed Dr. S. Dana Hubbard head of the Division of Industrial Hygiene under his new plan, which separates this division from the Bureau of Preventable Diseases, of which Dr. Louis I. Harris is the director.

Dr. Henry Dwight Chapin of New York has been appointed chairman of the Public Health Committee of Governor Smith's Reconstruction Committee, which has been organized to solve post-war problems.

Dr. A. L. Benedict, who has been serving as captain in the Medical Corps of the United States Army since November, 1917, has returned to Buffalo, and will resume his practice at 377 Elmwood Avenue.

Dr. Charles F. Dalton of Burlington, Vt., has been appointed to the chair of hygiene and preventive medicine of the University of Vermont, to succeed the late Dr. C. S. Caverly. Dr. Dalton also succeeds Dr. Caverly as president of the State Board of Health of Vermont.

Public Health Service Bill.—A bill appropriating $10,500,000 for enlarging hospitals to be conducted by the United States Public Health Service was reported favorably to the House by the Buildings Committee on January 25. A minority report opposed the program as unnecessary if abandoned army posts were converted into hospitals.

Hospital Equipment to Aid Polar Expedition.—The Aviation Committee of the National Special Aid Society has unanimously voted to contribute the complete hospital equipment and supplies for the Roosevelt Memorial Arctic Expedition, which is to start by airplane for the polar regions in June of this year.

Campaign for Tuberculosis Hospital.—At a meeting of the board of trustees of the National Jewish Hospital for Consumptives, at Denver, Col., held at the Hotel Biltmore, New York, on January 25, plans were announced for a campaign to raise funds among children of Jewish religious and Sabbath schools throughout the country to erect a children's pavilion as an addition to the institution. The annual report from the hospital shows that during the nineteen years of its existence it has cared for 3,500 tuberculosis patients, 70 per cent. of whom have either been cured or their disease arrested so that they were able to become self-supporting.

Health Congress in June.—Plans have been perfected for a public health convention to be held in June, in conjunction with the annual meeting of the American Medical Association. The Hotel Traymore in Atlantic City has been selected as headquarters for the meeting.

Civil Service Positions Open.—The Civil Service Commission of the State of New York announces the following examinations to be held March 1, 1919, for which applications must be received at the office of the commission before February 19: *Physiological Chemist,* at a salary of $2,600 to $3,000 a year. Applicants for this position must have had practical experience in physiological, biological, and organic chemistry. The position is open to men and women and to non-residents and citizens, except those at war with the United States. *Laboratory Assistant in Bacteriology,* at a salary of $720, open to men or women between the ages of 21 and 35 years. Only candidates who have completed a satisfactory course in bacteriology will be accepted. *Assistant Physician,* regular or homeopathic, to provide eligibles for the position of assistant physician in the State hospitals and for other positions of similar nature in various State and county institutions. The salary is $1,200, with increase and maintenance. The examinations are open to men and women who are licensed practitioners of medicine in New York State, and who have had six months' experience on the resident medical staff of a general hospital, or as a medical interne or clinical assistant in a State hospital or institution. No written examination will be required of applicants who meet the specified requirements.

Medical Society Elections.—THE CENTER DISTRICT AND MERRIMACK COUNTY (N. H.) MEDICAL SOCIETY, at its ninety-seventh annual meeting, held in Concord, N. H., January 14, 1919, the following officers were elected for the ensuing year: *President,* Dr. George E. Clarke of Concord; *Vice-President,* Dr. N. L. Griffin, New London; *Secretary-Treasurer,* Dr. Charles Duncan, Concord.

THE ANDROSCOGGIN (ME.) MEDICAL ASSOCIATION, at its annual meeting, held in Lewiston, Jan. 7, 1919, elected the following officers for the ensuing year: *President,* Dr. Harold Garcelon; *Vice-President,* Dr. Leo Hall; *Secretary,* Dr. A. S. Dolloff.

The Waterbury (Conn.) Medical Association, at its annual meeting, January 13, 1919, elected the following officers for the ensuing year: *President*, Dr. Charles H. Brown; *Vice-President*, Dr. Edward W. Goodenough; *Secretary*, Dr. William H. Licht; *Treasurer*, Dr. Charles S. Rodman.

The Winona County (Minn.) Medical Association, at its annual meeting in Winona, Jan. 7, 1919, elected the following officers for the ensuing year: *President*, Dr. F. H. Clay, St. Charles; *Vice-President*, Dr. Oswald Leicht; *Treasurer*, Dr. F. W. F. Heise; *Secretary*, Dr. High F. McGaughey.

The New England Women's Medical Association, at its forty-sixth annual banquet and meeting, held in Boston, January 16, 1919, the following officers were elected for the ensuing year: *President*, Dr. Agnes C. Vietor; *Vice-President*, Dr. Margaret L. Noyes; *Secretary*, Dr. Alice Bigelow; *Treasurer*, Dr. Isabel Kerr.

Obituary Notes.—Dr. John H. Lowman of Cleveland, Ohio, who returned from Italy a few days previously, died of complications following influenza, in the New York Hospital, New York City, on January 23, aged 70 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1877, and formerly professor of clinical medicine in the medical department of the Western Reserve University. He was a former president of the National Tuberculosis Association, and represented the American Medical Association at the International Conference on Tuberculosis several years ago. Dr. Lowman headed the first American Red Cross tuberculosis mission to Italy, arriving in December, and within a fortnight was stricken with influenza and compelled to give up his work.

Dr. J. M. King of Chewalla, Tenn., was struck by a Southern passenger train near his home on January 4, and instanty killed. He was 65 years of age and had been a practicing physician for 45 years.

Dr. George Nelson Dolbeck, a graduate of the Hahnemann Medical College, Philadelphia, in 1893, died at his home in New York City on January 22. He formerly practiced medicine at Port Chester, N. Y.

Dr. Thomas Lewes Riley of New York City, a graduate of Bellevue Hospital Medical College, in 1897, died in Bellevue Hospital, after a long illness, on January 24.

Dr. Charles H. Greenough, a graduate of Bellevue Hospital Medical College, in 1872, died at his home in Bayport, L. I., on January 22, aged 69 years.

Dr. Charles Henry Riley, a graduate of the University of Maryland School of Medicine, Baltimore, in 1880, died suddenly at his home in Baltimore of complications following an attack of influenza, on January 23, aged 62 years.

Dr. Thomas F. Harrington, a graduate of Harvard Medical School, in 1888, died at his home in Boston on January 19, aged 53 years. He was deputy commissioner of the State Board of Labor of Massachusetts, and in 1910 represented the United States at the International Conference on Hygiene and Health at Paris.

Dr. Edward A. Ingham, district officer of the California State Board of Health for the Central Coast District, died of pneumonia at Berkeley on January 2.

Correspondence.

FELLOWSHIP WITH GERMAN PHYSICIANS.

To the Editor of the Medical Record:

Sir:—I have thoroughly approved of your recent editorials as to German doctors, who, when peace is declared, it is reported, are actually proposing to come to America and enter into practice!

At the close of the "Appeal to the Civilized World" of the ninety-three German Intellectuals, among whom appear the names of von Behring, Ehrlich, Haeckel, Neisser, Roentgen, Rubner, Waldeyer, and Wassermann, all doctors, they say:

"Have faith in us! Believe that we shall carry on this war to the end as a civilized nation to whom the legacy of a Goethe, a Beethoven, and a Kant is just as sacred as are our own hearths and homes. For this we pledge you our names and our honor."

One of their thus accredited statements is that "the German army and the German people are one." Let us see what that army did.

The armistice requires the German army to point out the wells that they have poisoned! So far as I know, this is the only occasion in history in which such an act of barbarism has been *officially confessed!*

Their atrocities in Belgium, France, Poland, and Serbia are known to thousands of witnesses. Those barbarities were the work of the army, with which, we are assured, the German people "are one."

They initiated the horrible poison-gas warfare.

They permitted the "unspeakable" Turk, their welcome Mohammedan ally, to murder by wholesale the defenseless Christian Armenians, including thousands of women and children.

Yet poisoning wells, using poisonous gases, and murdering innocent civilians—men, women, and children—are all prohibited by solemn treaties signed by Germany. But treaties are only "scraps of paper" to Germany.

And after all these atrocities and these constant violations of international law do these German doctors dare to come here and propose to obtain a living here as medical practitioners?

Never was there a more insolent proposal. The Germans are whipped, but still defiant; beaten, but still unregenerate. Witness what Hindenburg said to his army two days after the armistice: "We leave the fight, in which for more than four years we have resisted a world of enemies, *proudly and with heads erect.*" They must be taught many stern lessons in humility instead of the haughty arrogance which has been their national trait for years. If they dare to come, I hope that no American doctor will ever take any such man by the hand, and that no American medical society will admit a single one to membership. They may be sure that few, if any, American patients will ever patronize them. Let them stay at home.

In time, when as a nation they have repented of their sins and brought forth fruits meet for repentance, and especially when a younger and better and cleaner generation has come on the stage, then, and not until then, may they be received into civilized society.

W. W. Keen, M.D.

1729 Chestnut Street, Philadelphia

ULNAR NERVE TENDERNESS IN LEAD POISONING.

To the Editor of the Medical Record:

Sir:—I have frequently had occasion to note that marked tenderness of the ulnar nerve, particularly in the right arm, is one of the earliest signs of lead intoxication. Not only is it to be found in acute cases, but also in many chronic cases which have otherwise cleared up. It would be interesting to learn in how far lead is absorbed through the skin and into the nerves and nerve lymphatics, thus accounting for localization of lead neuritis.

6. Pulmonary Tuberculosis and Insanity.—Irving J. Sands points out that: (1) from the medical and sociological aspects pulmonary tuberculosis and insanity have much in common. (2) Psychoses among tuberculous patients are infrequent and are usually either of the infective toxic type of reaction, or shown by the manic depressive behavior. (3) An analysis of 962 cases of psychoses coming to autopsy at the Manhattan State Hospital during the past eight years shows that 13.61 per cent. revealed active pulmonary tuberculous lesions, and that of these, 61.83 per cent. had been correctly diagnosed antemortem; in the remaining 38.17 per cent., however, tuberculosis had not been suspected during life. (4) The general therapeutic principles employed in the treatment of tuberculosis are equally applicable in the insane as in mentally sound patients afflicted with this disease.

12. Contribution to the Etiology of Yellow Fever.—Hideyo Noguchi describes a leptospira which he has succeeded in isolating by means of dark field examination of the blood, liver, and kidneys of laboratory animals inoculated with the blood of yellow fever patients, and also in the blood and liver of the patients themselves. By special methods, this organism was obtained in pure culture directly from the blood of yellow fever patients in a limited number of cases, as well as from the blood and viscera of experimental animals. The organism in its morphologic characters closely resembles the leptospira described in cases of infectious jaundice. It does not grow on ordinary bacterial culture media, and when grown on the special media employed it induces no macroscopic changes of the latter and may easily be overlooked. Only by a very thorough dark field examination of such cultures can the occurrence of the growth be ascertained. By inoculation of blood and emulsions of the liver and kidneys of infected guinea pigs, the infective agent has been conveyed from animal to animal without loss of virulence through eighteen successive series, and pure cultures of the organism are obtainable during the course of the infection from any animal of these series. Inoculation of cultures, derived either from inoculated animals or from the blood of patients, induced in guinea pigs, monkeys, and puppies, symptoms and lesions similar to those following the successful inoculation of guinea pigs with blood from yellow fever patients. Moreover, the organism recovered in pure culture from these inoculated animals retained its original characteristics. Many of the guinea pigs which did not succumb to inoculation with blood from yellow fever patients showed definite febrile reaction, some with a trace of jaundice, for several days, but soon returned to normal. Most of these animals later proved resistant to reinfection. A positive Pfeiffer phenomenon was obtained in the majority of instances with serum derived from convalescents from yellow fever in Guayaquil when tested with the leptospira isolated from cases of this disease or from infected animals, and this was also true of the serum of animals which survived experimental infection. Characteristic symptoms and lesions were induced in susceptible animals by inoculation with the filtrates obtained by passage through Berkefeldt filters V and N of the blood of experimentally infected animals, of the emulsions of the liver and kidneys of these animals, and of the cultures of the organism. Leptospira was demonstrated in the blood or visceral organs of the animals thus inoculated. Fuller details of this work will be published later.

6. A Case of Bence-Jones's Albumosuria with Lymphocytic Leucocythemia. Henry L. Heimann and C. Bawden Wilson, with Note by H. Batty Shaw.

3. The Use of Vaccines in Acute Influenza and Influenzal Bronchopneumonia.—W. H. Wynn comments on the timidity so frequently manifested in the use of vaccines for treatment. He considers the vaccine dosage recommended by the Conference held at the War Office last October, and adopted by the Army and Local Government Board, entirely inadequate and points out that in the treatment of influenza and its secondary bronchopneumonia Lord Fisher's advice is appropriate: "Strike early and strike hard." Every case should be regarded as serious and a dose sufficiently large to produce a satisfactory response within a few hours should be given when the patient is first seen. When the author first used vaccines in the diseases in question, doses as small as 5 million were given; and results, though occasionally good, were uncertain. Larger doses were then given, with better results. It is important that the first dose should be effective. The doses now recommended in acute influenza and influenzal bronchopneumonia are: for an adult man, 80 to 100 million pneumococci, streptococci, and *B. influenzæ;* for an adult woman, 60 to 80 million; for a child of 12 to 14, 40 to 50 million; for

a child of 2 or 3 years, 10 to 20 million. In deciding the dose, the size of the patient is more important than the age. The dose should not be reduced because of the gravity of the illness; and if the first dose gives insufficient response the next should be larger, doses being repeated on alternate days or even every day if required. It is rarely necessary to increase the dose, however, if 100 million are given at first. Wynn cites a number of cases in which this treatment has been given with satisfactory results and states that he has never seen any bad effects when the vaccine has been given early in the disease. A constant feature has been the drop in temperature, associated with general improvement in the patient's condition and slower pulse. In acute lobar pneumonia the respirations are slower *pari passu* with the temperature and pulse. In influenzal bronchopneumonia, if the respirations are rapid they are slowed with the fall in temperature, but in the serious cyanotic cases with slow respirations the rate is increased. These results, which are similar to those obtained for years in acute lobar pneumonia and other types of bronchopneumonia, can only be explained by assuming that the injection of an adequate dose of vaccine causes a satisfactory immunizing process. Considerations as to the possible harm caused by negative phases has deterred many from giving sufficiently large doses of vaccine, and in this connection the author reminds us that the doctrine of the negative phase was worked out in patients suffering from chronic localized diseases and not in patients with acute diseases. The former appear to be "sensitized" in a different manner and the explanation may lie in the different amount of infection in the two cases. Prophylactic injections have been given by the author to 230 persons, 100 million of streptococci and pneumococci and 50 million *B. influenzæ* being used as a first dose; after a week 90 persons received double these doses, and 140 received 200 million of each organism. In some cases a third dose of 400 million, and in a few a fourth of 800 million was given. The author points out that, as Wright has shown, vaccine therapy is highly successful when applied during the incubation stage; in fact, he considers this the best time to inject if it could be discovered in the individual. His observations have also led him to believe that moderately small doses of vaccine give some slight measure of protection and that an attack of influenza confers immunity for a limited period.

6. A Case of Bence-Jones' Albumosuria with Lymphocytic Leucocythemia.—Henry L. Heimann and C. Bawdon Wilson report a case in which there was a history of "albuminuria," shortness of breath, and cough for 14 days, with blood-stained expectoration. Patient was a married woman of 39 years of age, who stated that she had suffered from anemia for the past ten years and that eleven months previously her legs had begun to swell, but returned to normal size on resting. Her complexion was waxy and she looked wasted. The anterior abdominal wall was lax, there was ventral hernia, enlarged spleen and liver, and enlarged heart with "blowing" systolic murmur in mitral area. Nothing abnormal was found in chest. There was no albumin in urine but, on heating, a flocculent precipitate appeared which largely disappeared on boiling. Detailed examination of the urine showed that the case was one of Bence-Jones' albumosuria and this was confirmed by various tests. Further experiments were made with a specimen of urine and a saturated solution of ammonium sulphate, all precipitates giving the Biuret reaction, a phenomenon which, combined with the different increments obtained by coagulation, suggests that Bence-Jones' albumose is a complex of a number of albumoses. The total albumose excreted per diem was found to be 35.7 g. and the nitrogen content was equivalent to 1.09 g. per diem. The albumose therefore contained 3 per cent. of nitrogen, the unestimated N amounting to 0.32 g. per diem. Streptococci were found in large numbers and in pure culture in the urine, the strain proving very virulent to rabbits. No casts were found. Blood examination showed, Wassermann negative, r.c. 2,860,000, hemoglobin 59 per cent., color index 0.9, w.c. 8,000, lymphocytes 63 per cent. During the time patient was under observation, from July 22 to August 16, there was slight evening temperature; appetite was good but weight increased only 2 lbs. There were no deformities in spine or painful areas in long bones, no enlargement of lymph glands or metaplastic nodules. Heart condition improved and cough disappeared while in hospital. The chief features of the case were the presence of albumose in urine, with relative and total increase of small lymphocytes in blood, and absence of signs of malignant growths. The authors are inclined to regard the lymphocytic myeloma of Parkes Weber and Ledingham as identical with the lymphoid hyperplasis of the bone marrow described by Hopkins and Savory and to include the present case in this category. They point out that the enlargement of liver and spleen indicate hemapoietic disease They are tempted to ascribe the heart lesion to an endocarditis of streptococcal origin, and to speculate whether a pyogenic organism of this type can affect the bone marrow and lead to the production of a lymphoid hyperplasia. They are convinced that the case was one of albumosuria from the beginning, and that the albumin was really the proteose they found. It is possible that patient may have had true albuminuria during the periods of dropsy. Commenting on this case, Dr. Batty Shaw points out that the association of leucocythemia with Bence-Jones' albumosuria is of special interest, and that presumably the marrow has shared with other tissues in producing the picture of leucocythemia. If Bence-Jones' albumosuria were expressive of a pathological function of the marrow it should be more common in leucocythemia, especially in the myelocytic form. The coincidence is one which has not been met with before in his experience, nor is it much referred to in the literature. He concludes therefore that the association is purely an example of coincidence, or would be more frequently observed if greater care were taken in the examination of the urine in such cases.

3. Pulmonary Spirochetosis. A Preliminary Note on Spirochetes in the Sputum of Soldiers Admitted to Special Malaria Wards.—Captain J. A. Thomson examined the sputum of 79 military patients in a special hospital for malaria in England; in 39 cases spirochetes were found, and in 2 cases tubercle bacilli. While in charge of the laboratory, the attention of Captain Thomson was drawn to the frequent requests made by medical officers for examination of sputum for tubercle, and later, coming into direct contact with patients, he was able to study the conditions which had led to the suspicion of tuberculous infection. In addition to chronic debilitation, cough, and lack of progress towards recovery, many patients exhibited tachycardia after or without physical effort, shortness of breath after slight exertion, systolic cardiac bruits both at apex and at base—if not while at rest, after slight effort, low vasomotor tone, nervous debility, and fluctuating temperature a little above or below the normal line. The cardinal signs of malarial cachexia were not seen in these cases, the blood was negative both on admission and during stay in hospital, and there was no appreciable enlargement of spleen or severe anemia. However, most of the patients in question had already been treated with quinine. All were men invalided home from Salonica on account of malaria and all had spent months in hospital with occasional visits to depots. The author states that it was not easy to determine whether the men actually got fever at their depots, but in many cases they stated definitely that the attack was not like their old malarial attacks. Sputa varied in character, being in the majority of cases clear, jelly-like, and non-aerated; in a few cases it was purulent, and more often mucopurulent.

In three cases (all without tubercle bacilli) the sputum was blood-stained. Captain Thomson was able to continue his observations only for a short period of approximately three weeks, as he was then transferred to other duties. He is inclined to believe, however, that many men presenting the symptoms he had described get attacks of fever when exposed to the strain of camp life and that these attacks are frequently not malarial in origin. It is difficult to say how far the symptoms are due to organic degeneration of tissues produced during the acute stage of malaria. Such factors as the mental and physical strain of war service, and the possibility of trench fever or other infection, must be considered. At present, therefore, the author wishes simply to point out that chronic pulmonary (or bronchial) spirochetosis is present in many such cases. Whether it is a cause of the debility, or whether the debility merely affords favorable conditions for the development of the spirochetes, must be decided by further research. As far as the author could ascertain, the physical signs of the cases under consideration were of an indefinite character and there appeared to be no serious pulmonary lesions. The spirochete, which stains easily, has tapering extremities and gently undulating outline without spirals. It affects various attitudes, sometimes extended, often bent on itself; when numerous, the organisms appear entangled with each other. Captain Thomson's observations would seem to lend additional support to those of Castellani and Violle (see MEDICAL RECORD, January 11, 1918, p. 74).

The Treatment of Tuberculosis of the Lymph Nodes by the X-Rays and Injections of Camphorated Phenol.—F. Hercher declares that among the many treatments, operative measures are alone to be rejected. At the present time the treatment of choice is by radiotherapy. When its use cannot be resorted to the writer gives the following indications based, for that matter, on Calot's teachings. When the nodes are soft but not broken down, puncture followed by an injection of 2 to 5 c.c. of a solution composed of acid carbol., 30 grams; camphor, 60 grams; alcohol, 10 grams. The injections are repeated every second to fourth day. About ten injections will usually be required. In cases of hard, solid nodes softening should be brought about by daily injections with the above solution, with or without the application of poultices. When fistulæ exist ½ c.c. of the solution is injected every fifth day.

Congenital Retraction of the Ocular Bulb.—A. Rados reports two cases in which the mobility of the right eye was intact. The left eye offered a slight external strabismus with a complete loss of adduction. This was replaced by a movement of retraction of the bulb with a palpebral ptosis. Some differences in detail of the movements of the eye offered by the two cases leads the writer to the following conclusions, namely, that in one case the insertion of the right internal muscle was too far back, and in the second this same muscle had two insertions, being attached at an unequal level behind the point of normal insertion.

Radiological Diagnosis with a Distended Abdomen; a New Method.—O. Goetze, in an important article illustrated by thirty figures, sums up the technique and results given by a new radiodiagnostic procedure consisting in distending the peritoneal cavity with oxygen or simply atmospheric air. This causes a sort of dissociation of the abdominal viscera which then become accessible to radioscopy and radiography. For the introduction of the oxygen, the writer employs a special apparatus or injects the gas through lumbar puncture needles. A practised hand will readily determine when the needle has entered the peritoneal cavity. The point of puncture should be selected at from three to five centimeters below the umbilicus in the middle of the left rectus muscle, or below the costal margin outside of the hepatic dullness. Insufflation of from two to three liters of oxygen is easily tolerated in all cases. As to contraindications to the procedure, they are all serious disturbances of the circulation and respiration, acute or adhesive peritonitis (danger of perforating the intestine), etc. The gas is evacuated after radiography has been done. This procedure has not influenced the temperature nor pulse in over ninety cases in which it was resorted to. The illustrations show the really remarkable results obtained, revealing as they do peritoneal adhesions, ascites at the beginning, neoplasms of the viscera or abdominal walls, various forms of hernia (among others the diaphragmatic, whose diagnosis is always a difficult, not to say impossible matter), enlarged mesenteric lymph nodes, changes in the abdominal aorta, caries of the spine and pelvic bones, abscess, the shape of the lower cardiac limits, pericholecystitis, renal calculi, renal changes, splenomegalia, pathologic conditions of the bladder (simultaneous intravesical and abdominal insufflation), growths of the uterus and adnexa, pregnancy, etc., are all examples for the use of this procedure. The writer announces another paper for the near future, the present one being merely a preliminary one.

The Diagnostic Value of the Cerebrospinal Fluid by the Procedure of Floculation in Cerebrospinal Syphilitic Lesions.—E. Nathan and R. Weichbrodt conclude in favor of the procedure described by Sachs and Georgi, which offers a remarkable accord with Wassermann in the majority of cases. The floculation method is, therefore, characteristic of syphilis; however, this equivalence with the Wassermann reaction is especially real in the case of the blood serum and is less so as far as the cerebrospinal fluid is concerned.

November 14, 1918.

The Treatment of the Pulmonary Complications of Influenza with Calcium and Neosalvarsan.—A. Alexander has noted, as almost immediate results of this treatment, a cessation of the progressive extension of the process and a subjective improvement and ease in the respiration.

The Genesis of Initial Serous Pleurisy in Tuberculosis.—H. Grau discusses the exact meaning of the terms primary or initial pleurisy as employed in a clinical sense. It is well known, however, that these terms are applied in the vast majority of cases to pleurisies which are primary in appearance only. From the viewpoint of pathology a tuberculous pleurisy is usually secondary to the development of one or several pulmonary foci. Radiography confirms this fact as it reveals changes in the apices or disseminated foci in cases of mild pleurisy at its beginning. This latter form of tuberculosis, which Grau considers as a dissemination by way of the circulation (interstitial form of the French writers) is responsible for the majority of the so-called initial pleurisies. It also has a hematogenous origin.

Unconscious Hearing in Psychogenous Deafness.—J. Göpfert describes a procedure which reveals the audition both in simulators and true psychopaths. The patient is made to sing with a piano accompaniment. Then the pianist changes the key (from one-half to one tone or more) and if the singer is not really deaf, he is carried along by his singing and changes to the key given by the piano. By playing in varying strength one may, by this means, estimate the degree of dysacousia in a subject having an incomplete deafness.

December 5, 1918.

Injections of Saccharose.—Lo Monaco, professor of physiological chemistry in the University of Rome, answers some of his critics in reference to injections of saccharose in tuberculosis. He claims that with his students and followers he has shown that injections of saccharose have two different actions on the secretions—in small doses they increase and in larger doses they diminish them. The first action is the result of stimulation of the glandular epithelium, while the second is due to constriction of the blood vessels. Thus small doses increase the secretion of milk in both women and cows, while large doses check hemorrhage.

In fact, this property is readily exercised by the local application of saccharose. In the Policlinic at Rome surgeons keep these sugar solutions always on hand. In certain operations attended by deep parenchymatous hemorrhage, this solution is depended on to arrest the bleeding. The latter are also used entirely in animal experiment. Injections of sugar have a proved value in hemoptysis, acting promptly after other hemostatics have failed. The action of sugar solutions and powder on wound surfaces has long been known. The first experience with tuberculosis was made with soldiers who received injections which were seen to check night sweats, expectoration, and other symptoms of the disease. Dr. Luccherini, who made these injections, chose the worst cases for the experiment. Another follower was asked by Lo Monaco to test the remedy on civil cases and the injection was tested on a variety of types. In six cases of advanced second stage the results were encouraging as the expectoration was brought to a standstill. In general, daily injections sooner or later tend to arrest secretion, although many days may elapse before such result can be obtained. That is, in some cases sputum is no longer produced as long as the injections are kept up. A few have gone 6 months, and one begins to wonder if the patients have been cured. This has not yet been shown beyond doubt, but that such result is possible appears from the fact that sugar, however given, has power over unhealed wounds. From Tunis comes a report of an Arab who expectorated an enormous amount, the total averaging at least three pints a day, who after 25 injections had only 10 c.c. of sputum per day and was anxious to return to work.

La Presse Médicale.

December 9, 1918.

Use of Dead Grafts in Surgery.—Nageotte and Sencert refer to the grafting of dead connective tissue into living organism. A year or two ago the claim was made that the former could undergo revivification under such circumstances and the authors have tested the problem on dogs. They worked largely with tendons, resecting these and inserting sections of dead tendon. At the expiration of a certain period the animals were sacrificed and the grafted tendon could in no wise be distinguished from the others in the limb. By the microscope it was quite impossible to distinguish where the graft ended, so absolute was the repair. The site of the former graft answered to all the tests of living substance. The next step was with grafts in the large arteries and in a series of animals pieces of dead carotid replaced resected portions. Not an animal was lost in this series of experiments. The surgical integrity of the vessel was secured but unfortunately the formation of thrombosis could not be prevented and the functional result was as bad as it possibly could be. By perseverance, however, the authors finally obtained an ideal result, which they attributed to perfection of technique.

Periodical Fever with Tibialgia.—Bourcart and Laugier describe one more type of fever seen quite recently on the Eastern front. Ordinarily it would doubtless have passed for malaria but observation led to the discovery of its autonomy. The initial attack was that of a classical secondary malaria. The temperature, however, did not run so high and the attack lasted longer. Then the periodicity was seen to be unlike that of any type of malaria, and the attacks seemed to taper off until permanent apyrexia set in. During the febrile crises tibialgia was a pronounced symptom and pressure over the crest was intensely painful. This symptom is described at length and is the most burdensome one of the disease. Some of the patients were already paludics so that it was easy to exclude malaria. Quinine was freely used in all cases but it was impossible to ascertain whether it controlled the disease and the impression received was that recovery was spontaneous. Since tibialgia is a prominent symptom of trench fever the latter affection will at once be suggested and a bacteriological study will be necessary to distinguish between them. No studies of this sort were attempted by the authors and they are silent as to louse transmission.

Correspondenz-Blatt für Schweizer Aerzte.

December 7, 1918.

Treatment of Influenza.—Massini, of Professor Stahelin's clinic, gives some matured observations on this subject after having expressed himself somewhat pessimistically. The only satisfactory method is to divide the disease into clinical groups. In all cases it is very difficult to determine whether the remedy has really been efficacious. He asserts that quinine had no prophylactic value even if pushed to deafness. Alcohol, tobacco and garlic have also been used in vain as prophylactics. The mask is burdensome to some and its value is in doubt, perhaps because worn too long without changing. Mask wearers have been infected, but none yet severely. Of many alleged abortive remedies no one has made good. The coal tar synthetics relieve symptoms and not a single instance of depression from these bodies has been seen. In the treatment of simple influenza two objectives are present, to mitigate the disease and to abort pneumonia. Of many remedies tested the only kind to receive any recognition are the colloidal metals and of these only electrargol and a new colloidal silver synthetic which contains acridin. This seems superior to all others of its type and is harmless, however injected. It has shown some negative results and is clearly no specific. Pneumonia can only be treated by old plans, as wet packs and the bronchitis kettle. The hydrotherapy is that of typhoid fever. The digitalis group of remedies was used not only after pneumonia symptoms had developed but even as prophylactic. This seems justified by the chance of sudden heart failure. Strophanthus and caffeine are also used and massage of the extremities will revive the pulse in some cases. Venesection, saline infusion, and the Murphy drip—in fact all known resources—have been drawn upon, but only too often the case progresses steadily to death without response to treatment.

El Siglo Médico.

November 30, 1918.

Data for a History of Influenza.—A contributor to *El Siglo Médico* who has been consulting an old journal file of 1837 found therein the following list of alleged outbreaks of the disease beginning in the XIV century. The first outbreak recorded was in Italy in 1323, with a recurrence four years later. A third outbreak occurred in the same country in 1351. There was an outbreak in France in 1387, a fact of especial interest when the disease is said by some never to have appeared in that country until two centuries later. In the XV century France had a series of epidemics in 1403, 1410, 1411, 1427, 1482. Italy was visited in 1428. These visitations may not have been global. Not until the XVI century do we begin to hear of pandemics affecting the whole of Europe. Such pandemics are mentioned for 1557, 1559, 1574 and 1580. In some or all of these Asia was ravaged as well as Europe. The affection, however, does not appear to have been serious, although one historian believes that Madrid was devastated, the people taking refuge in flight. The first appearance in England was in 1658 when many old people lost their lives. It appeared in that country again in 1676 and 1679. Middle Europe was visited in 1676, 1679, 1691 and 1695. In the XVIII century there were two pandemics in Europe, in 1709 and 1729. In the latter year 908 persons died in London in the course of eight days in November. In 1742 it ravaged Middle Europe. In this century it began to be known as the grippe. In 1762 one of the worst pandemics occurred in Europe. In the city of Breslau the total daily deaths reached 100. The last epidemic mentioned by the author occurred in 1782. It was at this period that the Germans named the affection Blitzkatarrh. Data as to the features of these epidemics are chiefly lacking but in some instances the public was attacked *en masse* during very cold weather and the late fall and early winter seemed especially selected for outbreaks.

Dysentery in Germany.—In order to illustrate the ravages of dysentery in Germany, it is sufficient to state that in one week last fall there were 2975 cases with 518 deaths.—*Pathologia.*

Book Reviews.

Infection and Resistance. An Exposition of the Biological Phenomena Underlying the Occurrence of Infection and the Recovery of the Animal Body from Infectious Disease. By Hans Zinsser, M. D.; Professor of Bacteriology at the College of Physicians, Columbia University; Bacteriologist to the Presbyterian Hospital, New York; Major, Medical Officers' Reserve Corps, U. S. A. With a chapter on "Colloids and Colloidal Reactions" by Prof. Stewart W. Young, Department of Chemistry, Stanford University. Second Edition Revised. Price, $4.25. New York: The Macmillan Company, 1918.

The second edition of Zinsser's book contains several revisions and additions which bring it pretty well up to date. For those who are not familiar with this work it might be said that the author has succeeded in writing a treatise on immunity and infection that can be read with profit by the practitioner of medicine as well as the individual more especially interested in this complex study. The problem of infection has become so inextricably interwoven with resistance of the animal body that we cannot think of infection as separated from the reactions which constitute the various forms of immunity. Such is the basis of Zinsser's work. The subject is discussed from every possible angle, both theoretical and practical. Naturally in a book of this kind there occurs a large amount of theory, but it is all well digested by the author who gives expression to his personal ideas on debated points. Several chapters are concerned with anaphylaxis, a topic that has recently assumed considerable importance in view of the extensive use of serums and biological products generally. The chapter on therapeutic immunization represents the most recent advances in this line. The reader will find much of practical value here. The newer work on serum enzymes and colloids is included, the latter being contributed by Prof. Stewart Young. We certainly can recommend this text and deem it a distinctly worth-while addition to medical literature. It is printed on excellent paper, in clear type, and contains a most voluminous and carefully arranged index.

Clinical Diagnosis A Manual of Laboratory Methods. By James Campbell Todd, Ph.B., M.D., Professor of Clinical Pathology, University of Colorado. Illustrated. Fourth Edition, Revised and Reset. Price, $5.00. Philadelphia and London: W. B. Saunders Company, 1918.

Todd's book is a well-known and popular manual of laboratory methods. The present edition has been enlarged and includes much new material. The particular features which appeal strongly to the average reader are its essentially practical character and the attractive manner in which the context is presented. Long-winded dissertations on the theoretical phases and histories of the various tests are omitted, but sufficiently lucid explanations of the rationale of these procedures are made to give an intelligent conception of their value and limitations. The manual contains ten chapters, with an introduction which is devoted to a common-sense exposition of the use of the microscope. A chapter is assigned to each major subject, as follows: Sputum, urine, blood, stomach contents, feces, animal parasites, miscellaneous examinations, bacteriologic methods, preparation and use of vaccines, and serodiagnostic methods. In Chapter VII, on miscellaneous examinations, the author takes up such topics as pus, peritoneal and other serous fluids, cerebrospinal fluid, animal inoculation, the mouth, eye, ear, parasitic diseases of the skin, milk, syphilitic material, semen, and the diagnosis of rabies. The chapter on bacteriologic procedures, while not exhaustive, is comprehensive enough for routine clinical work. The chapter on vaccines includes—in addition to the usual bacterins—tuberculin, the luetin test, and the Shick test for immunity in diphtheria. The last chapter, on serodiagnosis, is written by Prof. Ross C. Whitman of the University of Colorado. The basis of immunity is given in short form, following which are the methods and apparatus needed in performing the Widal test, the complement fixation reaction for syphilis, gonorrhea and tuberculosis, and the cobra venom test for syphilis.

An appendix is added which contains formulæ for staining solutions, a list of apparatus for office laboratory equipment, weights, measures, etc., and equivalent temperatures on the Centigrade and Fahrenheit scales. The author has drawn freely from standard works, particularly in the matter of illustrations, which are numerous and well adapted. We can recommend this book as a very useful and handy manual for the laboratory worker.

Medical Electricity. A Practical Handbook for Students and Practitioners. By H. Lewis Jones, M.A., M.D., F.R.C.P.; late Consulting Medical Officer to the Electrical Department in St. Bartholomew's Hospital. Seventh Edition. Revised and Edited by Lullum Wood Bathurst, M.D. (Lond.), Physician in charge of Electrotherapeutic Department, Royal Free Hospital (Officers' Section); late Chief Assistant Electrical Department, St. Bartholomew's Hospital. With illustrations. Philadelphia: P. Blakiston's Son & Company, 1918.

This book is a fairly exhaustive treatise on the subject of electricity as applied to the practice of medicine. Much of the text is the work of the original author, whose grasp of the problem was very wide. The first part of the book is devoted to a detailed consideration of the different forms of electricity and apparatus, with methods of application of the latter. Following this is a chapter on physiological data, such as electrolytic conduction, ionic medication, cataphoresis, resistance of the body, the action of electrical currents on living tissues, and lethal effects. A chapter on general therapeutic procedures discusses the chemical and physical basis of electrical treatment and the effects of x-rays and radium. Mention is made of the value of different forms of light rays. The author then takes up the use of electricity in various system diseases, nervous, circulatory, respiratory, digestive, genitourinary, joints and tendons, special senses, and skin. An appendix is added containing a table of electrochemical equivalents and relative ionic velocities. The work is extensively illustrated with cuts of apparatus and explanatory diagrams.

A Practical Medical Dictionary of Words Used in Medicine, with Their Derivation and Pronunciation, Including Dental, Veterinary, Chemical, Botanical, Electrical, Life Insurance, and Other Special Terms; Anatomical Tables of the Titles in General Use and Those Sanctioned by the Basle Anatomical Convention; Pharmaceutical Preparations, Official in the United States and British Pharmacœpias and Contained in the National Formulary; Chemical and Therapeutic Information as to Mineral Springs of America and Europe, and Comprehensive Lists of Synonyms. By Thomas Lathrop Stedman, A.M., M.D., Editor of the "Twentieth Century Practice of Medicine," of the "Reference Handbook of the Medical Sciences," and of the Medical Record. Fifth, Revised, Edition. Illustrated. Price, $5.00 net. New York: William Wood & Company, 1918.

The appearance of a new edition of Stedman's Medical Dictionary has come to be a biennial event, not only expected but welcome. The fifth edition, now at hand, has been enriched by the addition of many terms fresh from the battlefield: even such solecisms find place as P. U. O. and D. A. H., which the author admits to his lexicon with much the same gesture with which the young lady novice in the biological laboratory receives a crayfish to dissect. The new editions of both the Pharmacopœia and the National Formulary, appearing since the fourth edition, have necessitated considerable revision, which has been conscientiously performed. While we may not possess the imagination credited to the American humorist who spent many spare hours reading the dictionary, wondering how the characters would turn out, we can easily fancy the great help this volume will be to the medical writer who wishes to enlarge his vocabulary without sacrificing philological correctness. Against all hybrid words, crude and barbarous terms of all kinds, Stedman sets his face; while he does not impair the usefulness of his dictionary by omitting any such expressions which may be in common use, he nevertheless indicates their meretriciousness and strives to lead the medical writer into etymologically correct modes of expression.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 19, 1918.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE meeting was devoted to the presentation and discussion of "Some of the Medical Problems in Aviation."

The Field of the Medical Research Laboratory at Mineola.—Lieutenant-Colonel EUGENE R. LEWIS made this presentation, reading a brief paper by Lieutenant-Colonel E. C. Seibert which he afterward amplified. He said that the work of the Medical Research Board up to July, 1918, gave an insight into what had been accomplished in a field of medical endeavor that, while explored to a small extent in the past, yet at the period when the air service of our country was fast developing into a great military factor was, in comparison with other fields of military endeavor, almost an unknown quantity. Experience in the British and French service was being accumulated slowly, at the expense of many wrecked lives and broken machines. The air medical service of our allies did much to work out the means by which conservation of efficiency could be accomplished, and it was found when their air reports reached us late in September, 1917, that they had determined many of the causes that led to the rapid deterioration of air forces early in the war and had pointed out ways to remedy the conditions which were so seriously reducing the efficiency of their flying service. It was only needful to give the figures of three years to point out the results of the application of medical study to these problems. In the first year of the war the inefficiency in the flying service amounted to 65 per cent. In the second year this was reduced to 30 per cent., and in the third to 12 per cent., this inefficiency not coming from wounds or accidents, but solely from the stress of the service and the effects of altitude. The speaker said he would not discuss the physiology of altitude work, but would present a series of motion pictures showing the apparatus and procedure by which the classification of the aviator was arrived at and by which might be easily diagnosed the onset of those fatigue manifestations which had been termed staleness and which was so manifestly the fundamental basis of inefficiency which became so marked a feature of the Air Service of our Allies. The Medical Research Board was formed early in September, 1917. On a visit to Toronto in August, 1917, information was obtained concerning those effects that caused such lowering of efficiency in the British Air Service. This was made the basis of a report to the Chief Surgeon, A. S. S. C., and by his direction the Medical Research Board was recommended to the Secretary of War and authorized September 26, 1917. By this establishment of a board devoted entirely to research the problems of investigation were begun. The field was new, and as the possibilities for its exploration developed the interest became most absorbing. It was safe to say that while this work was started as a military need, the value of these researches to medicine would in some measure offset the loss of many in their usual fields of work. One method in particular might be called the rebreathing tank. This apparatus gave these conditions which developed circulatory strain in a short time and called forth all the factors of compensatory reaction by which such strain was met. In the ordinary stress of daily life there must be at all times stress in greater or lesser degree which was not met by the body powers in the form of compensatory reactions. This apparatus gave to medicine an exact measurement of the powers of compensatory reaction possessed by the individual, and by means of this knowledge certain latent deficiency in such power of reaction could be definitely determined. This was particularly valuable in cardiovascular research and more might be promised by future investigation. The Air Medical Service was peculiar, a study *sui generis*, as man had never had a chance to be exposed to the conditions encountered in the air before and in developing this service pioneer work had to be done. In providing a suitable air force there were three subdivisions of the work to be considered, namely, selection, classification, and maintenance. (1) *Selection.* In determining a man's fitness for the Air Service his physical equipment only was the responsibility of the Medical Corps; all other attributes of the applicant were up to the discretion of the Aviation Board. All ocular, hearing, upper respiratory, lower respiratory, cardiovascular, abdominal muscular, skeletal, and nervous examinations were exacting and comprehensive. The motion sensing ear function was incorporated into this selective examination because it was realized that the flier, above all others, should have the full complement of special sensory equipment. The high standards originally set up had been adhered to, as there was neither paucity of applicants nor reasons leading to the improvement of the service indicating advisability of change. (2) *Classification* was introduced in order to furnish flying instructors and commanding officers of training schools with definite information that enabled them to know that individuals allotted for certain types of flying would probably stand up physically in that training. The devising of practical tests for the examination of large numbers of fliers within a relatively short period of time was the problem of the Medical Research Board. When these tests had been devised, their rapid application to the service was accomplished by sending to the medical examining laboratory units and special equipment each capable of completing about twelve medical examinations a day. By demonstrations and lectures at the Mineola Laboratory intensive courses of instruction were given to specially selected medical officers recruited from those who had demonstrated their special aptitude for this air medical work and who had already acquired familiarity with the peculiar physical demands upon the flier by work in the examining units where selection was carried out. An additional division of the work of the Medical Research Board was the carrying out of various research work. In this purpose the Mineola Laboratory was extensively engaged and equipped with specially devised apparatus and provided with special research personnel in the various departments. (3) The *maintenance* of the physical efficiency of the flier was the practical application at the front and in the field of the products of all the foregoing work. Early recognition of beginning wear and tear incidental to the flying service was the keynote of conservation and reconstruction of skilled fliers. The signs of beginning physical deterioration were protean and infinite in variety and intensity. State of mind as well as condition of body were intimately involved. The flight surgeon came into being as the culminating development of the Air Medical Service and was sent to the airdromes at the front and the flying fields throughout the country with the sole mission of acquiring intimate knowledge concerning the individual flier's fitness for flying duty from day to day. To aid this flight surgeon he was provided with a physical director recruited from an athletic club or college and a specially trained nutrition officer. The flight surgeon's service was solely the maintenance of the man in the plane at his full efficiency. Prior to being sent to the field for active service the flight surgeon was sent to the Mineola Laboratory and given the most intensive and extensive training and instruction embracing all the various medical activities and developments covered in selection, classification, and research. This sent him out with the best possible equipment for his peculiar pioneer work.

Col. Lewis then gave a motion picture exhibition showing the rebreathing apparatus, the tests for visual and auditory acuity, and motor coordination, for the measurement of fatigue, color vision, and also a number of psychological tests, as for steadiness, association of ideas, memory test, reaction time to vision and hearing, etc.

The Practical Value of Ear Studies.—Major LEWIS FISHER, M.C., U. S. Army, gave this demonstration, which was illustrated by motion pictures. He discussed the value of ear studies in general medicine and the relation of the ear to aviation. The reason he called attention to the ear was because in recent years they had come to realize that the internal ear was not simply an organ of hearing, the special auditory sense, but that it was the organ of another special sense, namely, the motion sensing function. This function of the internal ear was quite a mystery until recently, but when

it was recognized that the middle ear was a special sense its value was recognized immediately. A medical examination to determine a man's fitness for a special work depended upon the examination of his special senses, and if there was another special sense to be examined it afforded that much more help. In seeking for methods of examination of the various special senses the attempt was always made to imitate the physiology of that sense. This same principle had been applied in the effort to devise methods for testing the motion sensing function. Many accounts of airplane crashes given by pilots emphasize dizziness or vertigo, and hence the organ responsible for dizziness when the individual was whirled around, namely, the ear, was made the subject of special investigation. An apparatus was devised which reproduced all the various stunt evolutions of the airplane and by which it was possible to simulate all the subjective effects of the actual stunt. Since being whirled in an aeroplane produced identical effects with those resulting from being whirled in a laboratory device, such as the turning chair, they were furnished with an accurate and convenient means of studying the various vertigo effects of ear stimulation produced by evolutions in the air, and the deductions derived from this experimental stimulation were true and applicable to stunt flying. The facts gleaned were so exactly in accordance with our knowledge of the ear as a "motion sensing" mechanism that they were simply corroborative of certain well-known otological principles. The speaker then described the semicircular tubes as canals containing fluid so placed that they were at right angles one with another. Because of this arrangement no change of position of the individual was possible without producing some movement of fluid on one or more of the canals. Movement of the fluid in these canals sent messages to the brain which were there interpreted as body movement. When an individual was whirled, whether in a laboratory apparatus or an aeroplane, there was produced a circulation of this fluid in certain definite canals or planes. If the turning was suddenly altered or stopped, or if the aeroplane came out of a rotating maneuver, the fluid in the canals continued to move in its former plane by sheer force of its momentum. The circulation of the fluid by momentum was interpreted by the brain as body movement; but not being in accordance with the fact, the body having ceased to revolve, it constituted vertigo or dizziness, and was disturbing to the individual. Each semicircular canal, if stimulated, produced a vertigo in its own plane. Therefore, with the individual in an upright position, stimulation of the horizontal canal was much less disturbing or disabling than stimulation of the vertical canals. When a disturbing or disabling vertigo was induced in the vertical semicircular canals, the effect could be greatly ameliorated by bringing the vertical canals in a horizontal position, which could be done by bringing the head forward. Thus by experience the aviator learned to adapt himself to the changed position through practice. By the use of laboratory apparatus he avoided the danger incident to acquiring this dexterity by actual flying.

Major Fisher gave a motion picture demonstration explaining the relation of the vestibular apparatus to eye movements, nystagmus, and vertigo, and showing the pathways of communication from the auditory and vestibular apparatus.

The Ear and the Aviator.—Captain H. W. Lyman made this presentation, which was illustrated by motion pictures. He asserted that of all the problems in aviation none was more important than sensing motion. It was absolutely necessary for the aviator to have his motion sense. On the ground a man could get along even though his motion sense was impaired; as, for instance, the tabetic could walk by the aid of his eye, and the blind man could get along by means of the tactile sense; but the man in the air changed his position so constantly and so rapidly that it was essential that he have his motion sense unimpaired. He must be 100 per cent. perfect if possible, and for that reason the examinations of the special senses had been very strict. The first film to be exhibited was concerned with deaf-mutes in actual flight. As a rule the deaf mute was without vestibular mechanism. The fact that a deaf mute did not hear did not necessarily mean that he was without motion sense, because the cochlea might be destroyed without destroying the static mechanism. However, as a rule, in deaf-mutes the motion sense was destroyed. A comparison of the motion sense of deaf-mutes and that of normal individuals was made by having the deaf-mutes actually fly. They were supplied with paper and pencil and recorded their conception of the changes in posture that they experienced during flight, and these were compared with the actual course as recorded by a good aviator whose motion sense was normal. The films illustrated this comparison and showed that the records of the deaf-mutes were surprisingly inaccurate, and that they were unable to detect to any extent the movements of the plane. The second film showed an interesting piece of apparatus known as the orientator. In its construction it was like the cockpit of an aeroplane, suspended in concentric rings, after the manner of a ship's compass. The movements or changes of position were possible in all directions except actual forward progression and were governed by the individual seated in the machine and using a set of controls like those of an aeroplane. Strapped in this machine he was able to execute any evolution, at any desired speed for any number of turns, and thus acquire in absolute safety a tolerance for the disturbing effects of vertigo induced by the various evolutions, instead of acquiring this tolerance and knowledge by actual flying with its consequent crashes and loss of life. In this apparatus the student soon learned to orientate himself in new and rapidly changing positions of the body and to perform properly the complicated acts necessary to trol an aeroplane. A man instinctively learned to drive an aeroplane very much as he learned to drive an auto or to skate. The flier instinctively adopted means which at all times kept the vertigo in a horizontal plane—procedures based on sound otological principles. The greatest usefulness of the knowledge that stunting was an ear problem lay in the fact that the flier might be educated to disregard the vertigo effects of his stunts and by means of the orientator acquire a tolerance to evolutions to a large degree impossible in the air.

Dr. George D. Stewart said he confessed that he was instructed, interested, and very much amused by the presentations of the evening. He was much amused by the demonstration of the orientator. He had been instructed by the lucid description and graphic method of demonstration of the posterior longitudinal bundle —a structure he had always found difficulty in describing to his students. After thanking the gentlemen for having given them such a very interesting evening, Dr. Stewart said he would also like to thank Dr. James, as his term of office as President of the Academy drew to a close, for having given them such good meetings, he had kept—he would not say the good wine, since all wine was good—the best wine until now.

Dr. R. C. Myles spoke briefly of the great value of the work that had been presented, in that through it many lives were saved that would otherwise have been sacrificed while learning the art of flying. The work done at Mineola and the procedures carried out there could not be improved upon.

Dr. S. Adolphus Knopf asked if any observations had been made with reference to the effects of flying and high altitude on the pulmonary system.

Colonel Lewis replied that they had not much to report on that point, for if one stopped to think it was evident that whatever effect the high altitude had as a result of barometric pressure was transitory. Even if the aviator ascended to a height of 20,000 feet it was only for a few minutes, and it was obvious that under the conditions no examinations could be conducted that would carry much weight, and one could not expect much organic change as a result. There were, however, cardiac and vascular phenomena when a man exceeded the limit of his endurance, as acute dilatation of the heart, just as occurred in running when a man exceeded his limit, but they were also transitory unless they went to such an extent as to be fatal, but they had not seen any fatal results from such causes.

Dr. Louis Livingston Seaman related some of the experiences of a party of which Dr. Senn and he were members, who went to the top of the Andes, 18,000 feet above sea level. All of their party were seriously af-

fected after they had ascended 9,000 feet in six hours. Later they all became seasick, and two of the party were so seriously affected that this experience was thought to have hastened their death. These, however, were not young men like those engaged in aviation.

Dr. WILLIAM P. NORTHRUP congratulated the speakers of the evening on the excellence of their delivery as well as the instructiveness of their presentations, and spoke enthusiastically of the cinematograph as an aid in teaching, urging its more general adoption by the younger men who were engaged in teaching.

Annual Meeting, Held January 2, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

Report of President.—Dr. WALTER B. JAMES submitted this report, in which he stated that during the year 1918 all the usual activities of the Academy had gone on without interruption. The number of readers in the library had been somewhat fewer than during the few years preceding, due to the large number of the profession absent on military duty, but the falling off had been less than would have been expected. The war shortage of medical books and journals had continued and this had given rise to a considerable balance in the hands of the Library Committee, which would be expended when communication with Europe again became normal. In spite of the war, none of the stated meetings had been omitted, although a resolution of the Council permitted this to be done. An attendance at these meetings quite equal to that of other years testified to a growing interest in them on the part of the medical public. The project of building a fireproof addition on the adjoining lot had necessarily been held in abeyance through the war. The plans, however, were now being completed in detail, and the specifications were expected to be ready by the end of this winter, so that as soon as building costs and conditions made it possible work could be begun at once. The opportunity of having their dues remitted by those Fellows who were absent from their practice on national service had been largely availed of, but, in spite of this considerable diminution of income, and of certain unusual expenses, the academy had been able to meet all its obligations and to continue its operation throughout the year without deficit. The Academy Extension Fund was not quite adequate to build and equip the proposed addition, and it was hoped that the Fellows would subscribe additional funds to make this possible.

Report of Council.—Dr. WILLIAM L. STOWELL presented this report in which it was shown that the regular meetings of the Council had been held and the business of the Academy transacted. At the January meeting it was resolved to remit the dues of such Fellows as might be absent in the national service, and this privilege had been availed of by a large number. At the February meeting the Council endorsed the creation, on the part of the Pediatric Section, of a Committee on War Time Problems of Childhood of the New York Academy of Medicine. The Sections had in some cases been excused from having their regular meetings. The Council had had regular reports from the Public Health Committee covering its various activities and was pleased to find this committee occupying a constantly more and more useful and indispensable position in the community.

Report of Trustees.—Dr. W. GILMAN THOMPSON and Dr. NATHAN E. BRILL submitted this report, which stated that the Trustees had held their accustomed stated meetings during the year and, in addition, had held a number of special meetings for the transaction of the business of the Academy. Owing to the exigencies of the war conditions, there had been minor administrative difficulties. The loss of the Academy's income through remitting the dues of the Academy members while in war service had been offset by rigid economy and by additional funds which had been derived from the income of the Rudolph A. Witthaus estate. The most important financial transaction of the year had been the lease of the property of the Academy in the rear of the main building, with option to purchase within five years, under conditions which are believed to be very satisfactory to the Academy. Plans for enlarging the Academy's facilities through rebuilding upon the lot owned by the Academy and adjoining it, had not been lost sight of, but were necessarily suspended, owing to the inflated cost of all building materials during the year.

Report of Committee on Library—ROBERT J. CARLISLE presented this report, in which attention was drawn to recent reports of this committee as to the effect of the war on the Library's activities. The total number of readers was about 6000 less than in 1916, when the largest number of readers was recorded, 27,203. The total for the year was about the same as for the year 1912. In 1916, the number of volumes added was 3911, while for 1918 it was 900 less. There had not, however, been a corresponding reduction in the number of pamphlets, there having been more of these than for any year since 1912. It had been impossible to obtain the German and Austrian periodicals complete since 1914. A number of the 1915 journals had been accessioned, some through gifts of individual Fellows. There were at present some 1500 periodicals overdue. It was evident that the committee could look forward to a time, very rapidly approaching, when the former congested and overcrowded condition of the Library would again exist. The Library Committee requested an appropriation of $5,000 to cover Library expenses for 1919. The detailed report of the committee showed that from December 13, 1917, to October 31, 1918, 2,697 new books had been added to the Library.

Dr. WALTER B. JAMES, in relinquishing the Presidency of the Academy, said it was his duty to hand to his successor his office which it had given him so much pleasure to occupy during the past four years. It was difficult to do this without mentioning the loyalty of the officers and members of the Academy, which had made his term of office a constant pleasure. It was perfectly fair to say that he envied his successor because the duties of his office brought him into such close association with the members of the profession. The world was too busy looking to other things to give much attention to what was happening in medicine, but the members of the profession were intent on what was going to happen in the future; all believed that the science of medicine had a tremendous future ahead and the Academy of Medicine stood for all the greatest aspirations of the profession both scientific and spiritual and should, therefore, have a great part in that future.

Address of the President.—Dr. GEORGE DAVID STEWART, in assuming the duties of his office said that he would promise to make his remarks very short, that he meant to content himself with calling attention to the increased responsibilities of the teacher and practitioner of medicine in America today. Over a large part of the civilized world there was chaos, because the formulae of civilization had failed. This failure was nothing new, but had occurred again and again through the centuries; in England, in the reign of John, when the nobles wrested from their monarch the Great Charter; again in England, in the reign of Charles I, when it was necessary to separate that monarch from his head, and in France, in the great Revolution of 1789. In the French Revolution, civilization had broken down despite the fact that Roman law and Roman civilization had been introduced into France prior to the Christian Era, and had held sway there for several hundred years. The French believed they were struggling against the monarch. The truth was that people and monarchs were both victims of a vicious system; there had been a lamentable failure of education and of all the agents of civilization, which might or could teach the people how to ballast their Ship of State, or what course they were in the future to steer. Then they invented a new and specious formula, "Liberty, Equality, Fraternity," and the people waded through the bloody years of the Terror to prove that all men were born free and equal, or, rather, to prove that the proposition could not be proven. The same thing was happening again. We were witnessing this last colossal failure of civilization, and, as Henry Adams had said, political progress seemed to be only by assassination. Once more we were groping for ideals. "Pacifism" and "The League of Nations" were the new formulae that were being offered to us. To the pessimist they seemed much

like "Balance of Power," and few even of the optimists dared to hope that eternal peace could be achieved. When it came truly the millennium would have arrived, the lion might lie down with the lamb, and the child play on the cockatrice den. Until that event, even if we could not attain perfection, we were all the better for making the attempt just as the teacher might ennoble his soul by an effort which lulled his hearers into somnolence. The standards of medicine had always been high. Medicine had always borne on its banner an inscription to the "brotherhood of man," and it was our duty in this trying time to see that no lowering of these standards was permitted. During the war medical education in the warring countries had suffered tremendously, and on the profession of America had fallen, whether they wished it or not, great responsibilities. In keeping up these standards, indeed, in elevating them to higher levels, the New York Academy of Medicine had borne a worthy part, for which altruistic work the officers and committees of the Academy deserved hearty thanks, particularly the Public Health Committee, and the retiring President, Dr. James. Dr. James, by his vigilance had prevented any lowering, even under war conditions, and by his industry and influence had provided intensely interesting meetings, thus spreading the message of the Academy afar. In concluding, Dr. Stewart said he wished to thank the members of the Academy for the courtesy of electing him President; he would enter upon his duties with a haunting fear that he might not prove a worthy successor of Dr. James, and he would not dare the challenge, did he not feel that he could turn for aid and counsel to Dr. James and all the other officers and members of the New York Academy of Medicine.

Experiences of a Surgeon in the War Zone.—Colonel GEORGE E. BREWER delivered this address in which he related in an informal way some of his experiences in the war zone, discussing certain of the medical problems and activities and also the progress of surgery in the treatment of battle casualties. He said it was perhaps unnecessary to remind his hearers that the wounds of battle differed in character, extent, multiplicity, and in their mutilating effects on account of the extensive destruction of tissue and deadly infections, from the wounds met with in civil practice. Of all the disabling and invalidating sequelæ of wounds, infection headed the list, and, therefore, how to combat infection was the first problem that confronted the military surgeon. To give some slight idea of the progress in this respect, he recalled two mental pictures which had made a deep impression on him. In April, 1915, he had had charge of a small military hospital midway between Paris and Soissons, which was sometimes conducted as a base hospital and sometimes as a casualty clearing station. It was filled with every type of battle casualty. On his first visit to this hospital the impression made was one of almost universal infection of a virulent order. Up to that time, certainly, military surgery had not been able to cope with the type of infection observed on the battle front and as a result, the number condemned to a life disability or chronic invalidism was great. The impression which he compared with this was that obtained when he went to France a second time with the Presbyterian Hospital Unit and was placed in charge of British General Hospital No. 1. When he made his first visit to this hospital he saw the same types of battle casualties as before, but a very different picture was presented. Instead of the men lying listless and pallid and exhibiting all the evidences of sepsis, many of them were sitting up, looking bright and interested in what was going on about them. They presented a striking contrast to those seen on his previous visit, and he was simply astounded at the number of wounds absolutely free from infection. There were, of course, a large number of infections, but these were largely being controlled by the methods in use. Nearly every day cases were brought to the operating rooms to be closed by secondary suture. Shortly after this he spent a few days in the Belgian hospital conducted by Dr. DePage and there was practically no infection observed in the cases in that hospital. Another hospital which he visited had been unusually successful in treating compound fractures and in avoiding the anaerobic infections. Colonel Sinclair was particularly successful in treating compound fractures, especially those of the thigh. On the morning of his visit to his hospital, there were about 152 cases of compound fracture of the femur, all being treated by the Carrel-Dakin method, carried out with the most complete and perfect technique. With the exception of a few very recent cases and those with residual osteomyelitis, all were practically free from infection. He asked what was the shortest time that elapsed from the time the men received these fractures of the femur until they could be on their feet. Several men were called and questioned. These men simply wore steel braces and used canes. One said he was on his feet in six weeks and three days; a second said six weeks and five days, while a third said a little over seven weeks. These results seemed unbelievable, but they served to give some idea of the difference in the results obtained during the early years of the war and those seen in 1917.

It was singularly fortunate that our men entered the war after these results were acquired. What was the cause of this change? Three things of importance. First, both the French and the British realized that their original plan of having the major surgery of war carried out at base hospitals was wrong, that by the time a man reached a base hospital infection had a firm hold and that if good results were to be obtained the men must be operated upon as soon as possible after they received their wounds. When this fact was recognized they decided to push their operating hospitals up as near to the front as was possible and to man them with the best surgeons. The second important factor making for success was the perfection of the Carrel-Dakin technique. That method, if properly and thoroughly carried out, with carefully trained assistants, constituted one of the most important advances made in antiseptic surgery of the century. When anyone said that the Carrel-Dakin method was no better than other methods, it might safely be assumed that the method in that instance was not being properly carried out. The effective application of the Carrel-Dakin method required a great deal of time, many assistants and the most assiduous attention to technical details. The third most important factor was the recognition that there was a golden period between wound contamination and wound infection, generally estimated as the first twelve hours after injury, when the wound could be sterilized by operation—the so-called *débridement*—which meant cutting away all damaged and devitalized tissue and removing it with the foreign body and all infected material. If this could be accomplished, the wound, under favorable conditions, might be closed by primary suture. For this three conditions were essential: early operation, expert surgery, and a period of absolute quiet during convalescence. If these conditions were not possible delayed primary suture might be practised, namely, débridement, generally packing the wound with sterile gauze, and later closure, after four or five days if the wound remained clean, and the bacteriological examination was satisfactory. In cases in which the wound could not be thoroughly sterilized by operation, the injured tissue was removed as completely as possible as in the two preceding types of wounds, but in addition the Carrel-Dakin treatment was instituted. When later the condition of the wound was satisfactory as shown by the appearance and bacterial count, it might then be closed and one could hope for a satisfactory secondary union.

When our medical men first went to France there was the most cordial cooperation on the part of the British Medical Department and the French Service de Santé. They permitted our surgeons to go into their hospitals to observe their methods, and to work with them. All of this was most fortunate for our soldiers, for it was most important that our surgeons should gain experience in war surgery in hospitals already in operation. Colonel Brewer related that at first he was connected with an evacuation hospital in a quiet sector, Major Gibbin of Philadelphia, being in charge of another. Here they had a comparatively small number of casualties, from 10 to 30 a day, and when a raid occurred they might have from 100 to 150. They had splendidly equipped surgical teams and their results were exceedingly satisfactory. There was a

friendly rivalry between these two hospitals. In the first eight weeks, Hospital No. 2, of which the speaker had charge, handled 500 to 600 battle casualties, largely from high explosives, comprising all kinds of fractures, abdominal wounds, sucking chest wounds, brain wounds, and the various types of soft part wounds. Of these, 206 were closed immediately, and 93.3 per cent. healed without a drop of pus or a particle of infection. The second type of wounds in which they did not attempt primary closure were lightly packed for a certain number of days and closed by delayed primary closure. Of these, 100 per cent. healed without infection. In the third group where they knew infection was present, the Carrel-Dakin treatment was instituted immediately and secondary union was attempted; of these, 85 per cent. healed without suppuration. Major Gibbin reported almost identical results. This success was attained because of three conditions:

The patients were treated early; they remained in the hospital during the first eight or ten days after operation, and the surgeons who attended them were able and experienced. No matter how well trained a surgeon was in civil practice, he must be trained in a military hospital before he was fitted to do military surgery. A man must know just how far to go in débridement in each case, and this could be learned only by experience. To illustrate, Colonel Brewer said he had seen several cases of gas infection and thought he knew how to recognize it by the classical signs edema, odor, and subcutaneous emphysema, but if one wished to be successful in combating gas infection he must recognize it long before these signs appeared. On one occasion, he stood near a table where a young British surgeon was about to do an amputation of a leg. It looked to him like an ordinary compound fracture and he asked the young man why he proposed doing an amputation. The reply was, because of gas infection. He asked the young surgeon if he thought it was gas infection. The surgeon replied that he did not *think*, he *knew*, it was gas infection. He explained that he knew he was dealing with gas infection because the muscle had lost its color, being a brick red instead of a carmine—because the muscle fibers when cut did not contract, having lost their contractility, and because of the difference from the opposite side demonstrated by percussion. America had been fortunate in having had groups of surgeons in the evacuation hospitals who were not only skilled surgeons, but who had had experience in the treatment of battle casualties. Our Medical Department had its first great test at the battle of Chateau-Thierry, where we had eight divisions in the lines and our men were pushing back the Germans against the most stubborn resistance utterly regardless of the great number of casualties. Happily the third condition for the attainment of good results was present, that was that many of the best surgeons in America were doing the work, and that explained the success that was attained in spite of the delay in getting the wounded. He felt that under the conditions met with during and after the battle of Chateau-Thierry, there would be much gas gangrene, and in order to gain information on this point he had visited 26 base hospitals to ascertain what their results were in this respect. Much to his surprise and greatly to his gratification, the results showed not disaster but brilliant success. In three hospitals there was not a case of gas gangrene. One hospital had eight or nine cases, and a few had three or four cases; in all, there were about 30 cases of gas gangrene with 11 fatalities. As to the cases of delayed primary closure, they varied from 10 to 60 per cent.; about 30 per cent. could be closed within two or three days. The infected cases varied from 20 to 90 per cent., the average being 70 per cent., and of these about 85 per cent. were closed within six weeks by secondary suture. Although there was much delay in getting the casualties, the results were remarkably good, and for this there was only one explanation, and that was the good surgery at the front.

What was true of the Medical Corps after the battle of Chateau-Thierry was also true of the battles of Saint Mihiel and the Argonne. Colonel Brewer said that in his sector there were a great number of evacuation hospitals and surgical teams, and though there were many deaths and many amputations he felt that this was because of the conditions of war, which made it absolutely impossible to get all the wounded men to the hospital in time to save them. Many fell in shell holes and were not found for several days, and these men were hopelessly infected. There were also many bad compound fractures which it seemed impossible to clean up. At the battle of Chateau-Thierry the Americans had at first three large evacuation hospitals well back from the lines, because an evacuation hospital had to be situated at a rail head so that it could be evacuated rapidly. The roads were badly torn by shell holes, in spite of the large force of men kept busy all the time repairing them. There was also an enormous amount of traffic so that it was exceedingly difficult for ambulances to get through, and, consequently, there was great delay in bringing in the wounded, and as the number of casualties was very large, considerable time elapsed before the wounded received attention. The results of a rather far-reaching investigation made by the speaker allowed that the average time before the wounded received surgical attention was something like twenty hours. Another unfavorable feature with which they had to contend during this period, was the great congestion; at times every bed was filled, and there would be two or three hundred patients waiting, so many that in some instances they had to be turned over to base hospitals. The surgeons worked day and night and were constantly speeded up by being told how many were in urgent need of surgical attention. Under such conditions it was impossible for the surgeon to give the deliberate attention to each case that he could give in a quiet sector.

Colonel Brewer then spoke briefly of a phase of the war which he said was not strictly professional because he had so often been asked the question, "Do you think the German airplanes deliberately bombed hospitals?" On this subject he would not express his opinion, but would merely relate his personal experience, and his hearers might judge for themselves. In August, 1917, he was serving at a British front casualty clearing station. In this area they had a large number of surgical teams and many casualty clearing stations, several grouped together for the purpose of simplifying their administration, and because it was easier to deliver the ambulances. There were in the vicinity 15 such hospitals, each with 1000 or more beds. Some of these hospitals had been established for two years, many for a year, and none for less than six months. The Germans had photographed every inch of the territory just as we had photographed the area back of their lines. They knew where every hospital, every ammunition dump, every house was located and what it was. Every night a number of airplanes passed over the hospitals and no one thought they would attack them, as there were many legitimate targets in the neighborhood. On the night of August 17 they heard an airplane that seemed to be flying rather lower than usual. Suddenly they heard a terrific explosion, which was followed by a shower of debris. This bomb struck the officers' cook house, killing the night cook, wounding a medical officer and three nurses. On the same night three bombs struck in the center of another casualty clearing station, resulting in 66 casualties. Two or three nights after this four other evacuation hospitals were struck, causing numerous casualties. Two nights later their hospital was again bombed, killing 13 and wounding 35. In another hospital in which Dr. Darrach served there were 75 casualties. In still another group four hospitals were bombed on three successive nights. Within five days there were from three to four hundred casualties in the nine hospitals bombed. It was an insult to a man's intelligence to expect him to believe this was all accidental. Colonel Brewer related a number of very exciting and thrilling incidents in connection with these air raids on hospitals, and paid a tribute to the courage and self control of the personnel of the hospitals. In one instance in which they were compelled rapidly to evacuate, the nurses piled into the trucks that were to take them away singing as they came out. He had seen no instance in which any of the hospital personnel, medical officers, nurses, or enlisted men had failed in any duty, nor had he seen a single instance of lack of self control under these conditions.

SECTION ON SURGERY.

Stated Meeting, Held December 6, 1918.

DR. SETH M. MILLIKEN IN THE CHAIR.

Perforated Duodenal Ulcer.—Dr. EDWARD C. BRENNER reported a series of 11 cases of perforated duodenal ulcer, four of which showed something atypical as to history and signs. One case simulated intestinal obstruction, with very marked distention one hour after perforation occurred, evidently from cribbing of air and expelling it through the perforation. A second atypical perforating case simulated appendicitis with a diffuse peritonitis. A third showed the symptoms of general peritonitis suggesting pelvic origin. A fourth simulated appendiceal abscess. The operative measures advocated by the speaker was a simple closure without primary gastroenterostomy. All the patients in this series were examined before discharge after a six hour barium meal for gastric stasis. Two presented this condition, and in these a secondary gastrojejunostomy was done four weeks after the closure of the ulcer. These patients all remained well over periods of time ranging from two months to six years. The speaker also advocated immediate operation regardless of the degree of shock as the shock was relieved by opening the peritoneal cavity, thus relieving the tension. Drainage was not indicated if the operation was performed within twelve hours after the perforation and the peritoneum was not injected. The time of the operation in this series averaged 10.7 hours after the perforation, the shortest time being three hours and the longest two weeks. In only five cases was there a history of vomiting; the average temperature was 100° F.; pulse 90; white blood cells 15,000, and polymorphonuclears 85 per cent. Eight cases were cultured and all were reported sterile. Only two cases were drained. Obliteration of liver dulness was present in seven of the cases, absent in two, and in two this sign was not noted. This was a good differential point.

Duodenal Obstruction with Duodenojejunostomy.—Dr. EDWARD L. KELLOGG presented the following cases which were selected as illustrating variations in the problem of duodenal obstruction. In each in addition to the history and physical examination the diagnosis was based on complete data including the thread test, gastric analysis, urine analysis, motor function of the stomach, and *x*-ray examination. The pathology found at the time of operation was described.

1. *Duodenal Ulcer* (2 cases).—The first of these patients gave a history of having been operated on for appendicitis two years ago. Since that time the patient had had frequent attacks, with intervals of freedom from symptoms. The clinical diagnosis in this case was duodenal ulcer, dilated duodenum, pylorus not obstructed. At operation the cecum was found moderately dilated and adherent to the appendectomy scar, but not prolapsed. A small indurated ulcer was found just beyond the pylorus. The duodenum was much dilated. Just beyond the duodenojejunal junction the jejunum was narrowed, thickened, and there were light adhesions at this point. A duodenojejunostomy was performed, after which the patient made an uneventful recovery and had returned to work, being entirely free from all symptoms for a period of fourteen months. He had gained in weight from 129 to 142 pounds. This seemed to be the first case of duodenojejunostomy for the cure of duodenal ulcer (October 4, 1917). This operation seemed preferable to gastroenterostomy since the latter procedure must have been supplemented by pyloric exclusion and the obstruction of the duodenum would have remained. The *x*-ray examination in this case failed to demonstrate the dilatation of the duodenum. The second patient gave a history covering the past five years. The *x*-ray examination showed the presence of duodenal ulcer in this case. At operation the duodenum was found to be dilated presenting four fingers below the transverse mesocolon. There were adhesions to the gall-bladder. A crater-like depression was felt in the duodenum at about the junction of the first and second portions. The head of the pancreas was indurated and closely adherent to the duodenum at this point. The appendix was retrocecal, very long and closely bound down by adhesion. The procedure employed in this case was duodenojejunostomy, appendectomy, and plication of the cecum and ascending colon. The patient made an uneventful recovery, was entirely relieved of pain but had some intestinal fermentation. The *x*-ray in this case failed to demonstrate dilatation of the duodenum and no mention was made of dilatation of the cecum, although both conditions were evident upon physical examination.

Persistent Bile Regurgitation.—This patient gave a history of stomach trouble during two and one-half years. For this trouble hysterectomy was performed in 1915, followed by medical treatment for eight months. Cholecystostomy was performed in March, 1917. No stones were found and no improvement followed. This patient complained of burning in the stomach, esophagus and tongue, very severe, and every week or two vomited large quantities of bile. In the interim she frequently regurgitated it. The clinical diagnosis was intestinal adhesions, dilated duodenum with pylorus patulous or non-resistant, hyperesthesia of the esophagus. The *x*-ray examination showed a duodenal ulcer. A laparotomy was performed which revealed the omentum adherent to the scar of the old laparotomy and adhesions of the hepatic flexure of the colon involving the gall-bladder and duodenum. The duodenum was dilated, extending three fingers' breadth below the attachment of the transverse colon when the latter was drawn upward into the wound. The pylorus was dilated. No ulcer was demonstrated. The adhesions were divided and a duodenojejunostomy performed. The patient had ceased to vomit and regurgitate bile and was otherwise greatly improved. This was the type of duodenal obstruction with incompetent pylorus, shown by the regurgitation of large quantities of bile without pain.

Symptoms of Distention.—This patient had been operated on three years before for a floating kidney, the gall-bladder was inspected and found normal, and the appendix was removed. The symptoms were relieved for two months, after which a series followed of four attacks characterized by severe colic-like pain across the upper abdomen extending up under the sternum, and a more constant steady pain due to distention. During these attacks the temperature was subnormal; mental depression was marked; constipation was stubborn. Physical examination showed the abdominal walls relaxed; diminished resistance in the right iliac fossa; the right kidney could be palpated; there was gurgling and splashing in the cecum; the stomach extended from the fifth rib to the navel. The dilated duodenum could easily be made out by percussion. The pressure paradox (Hayes) was present. The *x*-ray examination showed adhesions of the duodenum which probably involved the gall-bladder and the terminal portion of the duodenum, obstructing this structure when the patient was in the upright position, and causing dilatation of the duodenum, ptosis of the cecum, and a probable band or membrane constricting the beginning of the ascending colon. In view of the severity of the attacks surgery was recommended at once. At operation the cecum was found markedly dilated and prolapsed into the pelvis. The hepatic flexure had given away completely, so that traction on the cecum caused a direct pull from the splenic flexure across the mesentery, resulting in pressure at the duodenojejunal junction. The duodenum was markedly dilated, the lower border of the transverse portion protruding through the mesentery four fingers' breadth below the attachment of the colon when the latter was lifted out of the abdomen. There was a long ligament of Trietz bringing the jejunum well forward on the surface of the mesocolon. The procedure followed here was a longitudinal plication of the cecum and ascending colon, restoration of the hepatic flexure and anchoring of the cecum to the posterior abdominal wall; duodenojejunostomy. This patient made an uneventful recovery; her bowels were moving regularly; duodenal symptoms had disappeared entirely, and she was gaining in weight and strength. Her mental depression had disappeared.

Epithelioma of Upper Lip. Excision and Cheiloplasty.—Dr. GEORGE H. SEMKEN presented this patient, a woman, sixty-five years of age, who noticed a small lesion on the left side of her upper lip, above the mucocutaneous border, in the late summer of 1916. Superficial erosion and crust formation soon occurred; and

there has been a progressive increase in the size and extent of the lesion. On May 23, 1918, when this patient came under observation, she had an elevated, indurated, elliptical lesion, 2.2 x 1.6 cm. in diameter, occupying the left half of the upper lip, including the mucous membrane in part, and extending for 1 cm. upon the adjacent part of the skin of the cheek. Its surface was covered by a thin, dark, reddish-brown crust. There were no palpable lymph nodes. (Photographs were shown.) On June 10, 1918, under local anesthesia, the lesion was widely excised—the line of section beginning near the midline and extending laterally well upon the cheek. The left half of the lip was removed *in toto*, excepting the upper half of the inner mucous membrane. For the closure of the defect that resulted a suitably shaped flap was cut from the left cheek, the pedicle being above, and this flap was swung mesialwards into place. A small triangle of skin had to be removed from above the defect to enable this swing to be made. The lower edge of the flap, where it became part of the mouth, was covered with a strip of mucous membrane, cut from the outer corner of the lower lip and turned back upon itself so as also to form the new corner of the mouth. The crescentic defect remaining upon the cheek was provisionally covered with Thiersch grafts. Three weeks later this crescentic area was excised, the skin edges were undercut, a small triangle was removed from the posterior arc (to reduce its length), and the wound area was closed by suture, thus leaving an inconspicuous curvilinear scar. The pathological examination of the tumor showed it to be a basal celled epithelioma.

Bilateral Mammary Carcinoma Presenting Unusual Features.—Dr. SEMKEN also presented this patient, a woman forty-seven years of age, who discovered a small tumor in the left breast in November, 1916. Four months later, when the growth had reached the size of an olive, an incomplete radical operation was performed upon the breast and axilla in a hospital in this city. Two months later a recurrence was noted in the line of the scar. Nothing further was done until October, 1917, when *x*-ray treatments to the chest and neck were begun; and these had been continued once a week until her admission to the Skin and Cancer Hospital on March 5, 1918. The local condition noted at that time was as follows: There was a short cicatrix, about 6 inches in length, across the upper chest and over the axilla. Near the sternal end of this was a raised ulcerated and indurated circular mass, 3.5 x 4 cm. in diameter, and about the end of the scar mesially a flat infiltration. There were palpable nodes in the axilla and in the left supraclavicular space. (Photograph shown.) On March 7, 1918, a comprehensive radical operation was done upon the left chest wall, axilla, and the supraclavicular space. Part of the sternal end of the third costal cartilage was resected also. The axillary nodes were bluish in color, and the largest one, approximately 1.5 cm. in diameter, was so closely adherent to the axillary vein at the site of the acromiothoracic vessels as to resemble a thrombosed varix. The supraclavicular nodes were all enlarged and black in color. Healing was uneventful except over the sternal end of the third costal cartilage and the rib end of the fourth, both of which had been covered with Thiersch grafts. The upper had since closed, and the other sinus would probably be healed soon. The report of the pathologist upon the material removed at operation showed carcinoma in the tumor of the chest wall, but none in the axilla or the neck. These nodes showed extensive pigmentation. The pathological condition of the right breast and axilla was first noted in September, 1918. There was then an olive-sized, projecting, hard, rounded, nodular, movable mass in the lower right axilla, just above and external to the breast; and a flattened fibro-adenomatous area in the outer part of the breast. The axillary tumor and a small piece of the suspected breast tissue were removed for microscopic examination on September 17, 1918. This study showed carcinoma in the node and fibrocystadenoma in the breast tissue. Three days later the radical operation was performed upon the right chest wall and the axilla. The report of the pathologist upon the tissue so removed showed a small focus of carcinoma in an area of intracanilicular fibroma of the breast. None of the other axillary nodes showed carcinoma. Healing was uneventful. A critical study of this case in retrospect brought out several points of interest: (1) The absence of carcinoma in the enlarged left axillary and supraclavicular nodes, and the operability of a seemingly inoperable condition; (2) the unusual pigmentation in the nodes, for which no explanation is offered; (3) the evidence of low resistance and poor vascularity in the costal cartilages, and their need of effective tissue-covering after operative exposure; (4) the occurrence of a malignant change in a benign process, as shown in the right breast—a phenomenon well known, but not often so well demonstrated; (5) the large metastatic cancerous axillary node, secondary to the minute primary focus in the right breast; (6) the failure of the probatory excision in the right breast to reach the cancerous focus, and the demonstration of the possibilities of error in such examinations; (7) the apparent independence of the cancerous process in the right breast from that of the left. Dr. Semken gave a demonstration of microscopic slides of (1) the recurrent carcinoma of the left chest wall, showing no pigment; (2) the pigmented supraclavicular nodes; and (3) the malignant change in the benign fibroma of the right breast.

Chronic Duodenal Obstruction. (Lantern Slides.)—Dr. EDWARD L. KELLOGG made this presentation. He first reported his findings from an anatomical point of view, which, he said, taught us that the duodenum was placed at a disadvantage in the matter of drainage and was easily subjected to mechanical interference. Writers on this subject gave one the impression that the condition was obscure and the diagnosis impossible unless made by the *x*-ray or after the abdomen was opened. It was his belief, however, that the condition was frequently present and the diagnosis could usually be made by the history and physical examination even in cases in which it was not demonstrated by the roentgenologist. It was certain that a considerable degree of obstruction might exist without symptoms. A study of the clinical cases showed two sets of symptoms, *toxic* and *mechanical;* in some both were present, in others only one group. One or more of the toxic symptoms were usually in evidence, *i.e.* headache, mental depression, lack of strength, disturbed heart action, cold extremities, and skin eruptions. The mechanical symptoms in obstruction of the first portion only were those of partial pyloric obstruction. In obstruction of the second and third portions, the mechanical symptoms would vary according to the problem presenting. Two distinct points of discomfort had been observed. First, a pain or dull ache just at the left of the median line and slightly above the navel (presumably the duodenojejunal junction); second, pain located to the right of the median line and above the navel, extending up under the liver and to the back. It might be colicky or steady and dull, often lasting until relieved by vomiting. It seemed possible to differentiate the following types of duodenal obstruction: (1) The asthenic duodenum, with symptoms largely toxic. (2) Duodenal obstruction with incompetent pylorus. (3) Obstruction with hypertrophy, the duodenum becoming elongated and the walls thickened (the writhing duodenum). (4) Dilated duodenum. The majority of these cases were amenable to the treatment given for enteroptosis or intestinal stasis, namely, abdominal support, sleeping with the foot of the bed elevated, resting after meals in the recumbent position, abdominal massage, colonic irrigations, mineral oil, cathartics, rest cure combined with forced feeding, etc. Those not responding could be cured by a surgical procedure which would vary according to the etiology of the case: dividing adhesions or shortening the gastrohepatic omentum for obstruction of the first portion; dividing adhesions for obstruction of the second portion; duodenojejunostomy usually met the indications for obstruction of the third portion or some operation on the cecum and ascending colon when the condition was plainly secondary to drag of prolapsed bowel and dilitation was not excessive. In spite of the fact that gastroenterostomy had been beneficial in one of his cases he considered the procedure obsolete, believing that when dilitation was marked the operation of choice alone or accompanied with other indicated procedure was duodenojejunostomy. It was only slightly more difficult than gastroenterostomy, the technique being much the same. In the writer's series of cases there had been no mortality.

and in every case there was either improvement or complete relief of symptoms, although sufficient time had not yet elapsed to speak definitely of end results. The following suggestions were offered: (1) Acute postoperative dilatation of the duodenum was predisposed to by chronic condition and might be prevented by correcting the latter. Vicious circle after gastroenterostomy was due to duodenal obstruction already present or produced by the operation. (2) In performing gastroenterostomy, if the duodenum is dilated, a duodenojejunostomy should supplement the procedure. Many socalled bilious attacks might be caused by obstruction of the duodenum, following constipation and the drag of a prolapsed omentum. Chronic duodenal obstruction probably predisposed to duodenal ulcer. In operating for duodenal ulcer when the pylorus was not obstructed and the duodenum was dilated, duodenojejunostomy appeared to be the proper surgical procedure.

Lantern Demonstration of the Pathological Duodenum; A Type Frequently Overlooked.—Lieut. Commander HAROLD D. MEEKER gave this demonstration. He stated that occasionally a patient presented himself to the general practitioner with symptoms referable to the upper abdomen which were quite atypical and did not respond to persistent medical effort. Should such a patient be seen and the suspected ulcer, neoplasm, galistones or inflammatory condition not be found, most surgeons would remove the appendix and attribute symptoms to the convenient and much abused reflex. Many such cases might be explained by the presence of certain abdominal bands which interfered with function. Whether the presence of these bands was due to embryological abnormalities, to infection, to an attempt of nature to hold up a sagging organ or to the selective affinity of toxins was of far less importance than the relief of symptoms. In observations on several hundred cases the speaker made the following arbitrary classification of these bands. (1) *a* Hepatoduodenal. *b*. Cystoduodenal. *c*. Hepatocystoduodenal. (2) *a*. Hepatogastric. *b*. Cystogastric. *c*. Hepatocystogastric. (3) *a*. Hepatocolic. *b*. Cystocolic. *c*. Hepatocystocolic. *d*. Gastrocolic. (4) Irregular. The speaker then gave a lantern-slide demonstration of the various types of bands, the points of strain and constriction, and described the resulting symptoms. The technique of repair was shown and stress laid on the necessity of using very fine round needles and fine suture material. Linen was used, treated with paraffin oil to block capillarity and to favor sliding through the tissues without tearing. The importance of covering raw surfaces and the inversion of raw edges was emphasized.

Dr. ANTHONY H. HARRIGAN said, that in regard to the diagnosis of duodenal ulcer, about a year ago he made a short contribution to the *Annals of Surgery*, in which he described a sign distinctive of the condition. This sign consisted in a small area of tympany over the liver, in the right parasternal line. It must not be, in any manner, confused with obliteration, or liver dulness. He believed that the sign was caused by the imprisonment of air, lying beneath the dome of the diaphragm and walled in by the falciform ligament. He did not maintain that this sign was found in 100 per cent. of the cases, but it was quite frequently present and was of great value in the differential diagnosis. While the suturing of a perforation of the pylorus was easy, yet he found the duodenal perforation one extremely difficult to suture. This was partly because of the presence of excessive exudate and fluid and the fact that the duodenum was relatively immobile. On the other hand, the stomach was quite mobile, could be delivered outside the wound, and easily sutured. Having found suturing in this locality so difficult, he usually employed gauze packing. He spoke of this to ascertain what the experience of others had been. In regard to the actual mortality in these cases, numerous articles detailing ten or twelve cases reported one or two deaths. In those met in general hospitals, such as the Bellevue and the allied hospitals, it was possible that out of eighteen cases the mortality was much higher. Some of these were operated on the second or third day, and some four or five hours after perforation. Dr. Kellogg had brought up the important topic of the surgical physiology of the duodenum. The question of chronic duodenal dilation was one to which Lane has given great attention. Those who had visited Lane in the Guy's Hospital in London would recall the *x*-ray pictures he showed to all his visitors of a case of chronic dilatation. Dr. Harrigan believed that Kellogg still left the etiology of this condition in the dark. A condition like that of of acute dilatation of the stomach, with which dilatation of the duodenum was usually associated, as yet had not adequate theory. In conjunction with Dr. Joseph Byrne, he had conducted a series of experiments on cats, repeating the experiments of Draper, Whipple, and Bernheim, of duodenal obstruction. The duodenum had been obstructed about 8 c.c. below the pylorus. The object of these experiments had been to determine the actual alterations in the nervous system. As yet, the experiments had yielded but negative results; however, it was interesting to state that intense hypermobility of the duodenum could be easily elicitated by electrical stimulation. This point was comparable to the writhing duodenum, described by Kellogg. It was possible that the whole question had a physiological basis. One must recall the theories advanced by Keith regarding the occurrence of nodes in the duodenum. Keith compared the entire intestinal tube to the heart. It was in the socalled myenteric plexus, which was supposed to initiate the impetus causing the movements of peristalsis. Dr. Harrigan wished to compliment Dr. Kellogg on his able paper.

Dr. FENTON B. TURCK said we were used to the surgeon, as a rule, presenting the anatomical pathology, that was the structural or architectural changes in the organism, and basing his deductions from these architectural changes. The great defect of this method of approaching the study of these changes was that these were not the disease, but merely the end product of the disease, and did not give any idea of the process or condition which we designated as disease. Dr. Kellogg's paper has been one of the most illuminating that he had listened to in this Section, particularly in that it presents both phases, the anatomical and the physiological. It was based upon complete data, including *x*-ray and other examinations both before and after operation, and a careful and methodical analysis of the condition clinically as he had done upon observations made in the course of animal experimentation. In the experiments which he had carried out in Chicago many years ago he obtained various degrees of obstruction of the alimentary canal at different levels. He found that obstruction in the lower part of the alimentary canal produced no marked symptoms, but when he produced these obstructions higher up they were followed by very marked symptoms with angulations. Seventy-five or 80 degrees of angulation were without symptoms if provision was made for the venous return. That was an important point that Dr. Kellogg brought out when he called attention to the line he had noticed on the duodenum in instances where he had obstructed the circulation affecting the splanchnic vessels. Now the question arose, "What made these symptoms?" Dr. Kellogg had had such excellent results by his operation in which the drainage was complete. This was a point the speaker observed in his experiments on animals; if drainage was adequate death did not occur in the animals operated upon. In the methods he had used he found that there resulted a much more rapid autolysis in the upper than in the lower part of the intestinal tract, for the reason that the ferments crypsin and trypsin were present in greater amounts in the upper part of the alimentary canal, and because of this there was a greater amount of proteolysis with resulting toxins. In his experience he took material from the stomach of animals and, after allowing it to autolyze for twenty-four hours, injected it into other animals, with the result that the animals died in three minutes; in others, in which a smaller amount was injected, death occurred after twenty-four hours, while control animals did not die. From this he had concluded that toxemia and death were due to tissue autolysis. Dr. Brenner found that after perforation there was shock and this was due to the absorption of the autolyzed tisue. He also found that in several of his duodenal ulcer cases with perforation that, several years after perforation, there was no return of symptoms, and this was because where there was perforation of an ulcer

with recovery there occurred an autovaccination. He had now produced a vaccine and a serum consisting of autolyzed tissue and bacteria especially for operative cases. This point was brought up because it was a very interesting fact that we never had a recurrence where the perforation of an ulcer with recovery had taken place. In these cases Dr. Kellogg had mentioned the medical treatment based upon restoration of the circulation and the overcoming of toxemia, which was a most reasonable procedure in all these cases both before and after the operation of duodenojejunostomy.

Dr. GEORGE WOOLSEY said that when Dr. Kellogg first presented his patients he thought his subject might be obstruction due to ulceration, and he wondered at that as we saw very few cases of obstruction due to ulceration. There were some cases of hour-glass duodenum reported as the result of ulceration, but they were rare. Dr. Kellogg said he regarded ulcer not as a cause but as a complication of the condition, as a rule. The method of determining dilatation of the duodenum by percussion did not appeal to the speaker. In the duodenum we had an organ situated posteriorly and surrounded by a group of hollow viscera, which made it difficult in percussion to know whether the percussion tone was from the duodenum or not. A vicious circle after gastroenterostomy might be cured by the union of two loops of the jejunum, so that it did not seem to be necessary to do a duodenojejunostomy. Dr. Woolsey asked Dr. Kellogg whether the duodenum to which he sutured the jejunum was covered with peritoneum or not. As he understood, Dr. Kellogg incised through the mesocolon and the duodenum was there retroperitoneal. If there was no peritoneal covering, the operation would not be as safe as an anastomosis operation where there was a peritoneal covering. The cases of perforating duodenal ulcer were an interesting series. Dr. Turck had mentioned that in duodenal ulcer the perforation seemed to cure the ulcer, but this was not invariably true; he had seen several cases in which there was subsequent trouble following perforation, indicating its continued existence, so without a gastroenterostomy we were not sure of avoiding further trouble. The suture of the ulcer or its cicitrization might cause a stenosis which would demand a later gastroenterostomy, so that he preferred always to add a gastroenterostomy if the patient's condition justified it.

Dr. ROBERT T. MORRIS said he was not present to see the cases or hear the first part of the paper, but it seemed to him that when a patient had any of the conditions named one should ask what else the patient had besides these conditions. The conditions described this evening were not diagnostic entities. They stood in second or third rôle to some underlying physical condition. Many of these patients might be grouped in the class with stigmata of arrested development, neurotic by inheritance and neurasthenic later. Duodenal lesions might relate to anatomical mechanical fault or to pathological processes, many of the latter relating to selective affinity for toxins. The subject of toxic peritoneal signs was brought forward by the speaker the very same year in which Lane called attention to his kinks as toxic insignia. The speaker had called the adhesions involving gall bladder and pylorus "cobwebs in the attic." The Lane kink first attracted attention and now, fifteen years later, cobwebs in the attic of the abdomen were receiving attention. Dr. Rosenow and Dr. Turck had both emphasized the importance of toxic influences, including autolytic changes belonging to antibodies called out in excess. The work Dr. Kellogg described was very neat. In many cases adhesions covered such a large area that one could not prevent recurrence of adhesions by such simple means. The speaker's first choice for preventing recurrence of adhesions was the employment of the Senn omental graft, next the use of Cargile membrane, the third, the arstol film. Dr. Kellogg described cutting of adhesions rather than tearing them free. One was always tempted to tear them, but that left a large surface for readhesions before endothelium could cover the defect. Neat cutting was better than tearing where one could employ the latter procedure.

Dr. A. JUDSON QUIMBY brought out several important points with respect to the *x*-ray examination of the duodenum. First it was very important to have the patient constipated when one made the *x*-ray examination. In the second place, the patient must not be handled too roughly in making the examination. It is frequently difficult to make the duodenum fill, as there may not be sufficient tone to carry the fluid ingested into the duodenum. In the third place, by putting the hand back along the middle of the fundus and carefully manipulating the stomach the organ can be held well up while the exposure is being made.

Dr. BRENNER said he was not sure of the exact area to which Dr. Harrigan referred, but he thought it was probably the same area of liver dullness to which he had referred. In regard to the mortality there were several factors that entered in: (1) The condition of the patient. (2) The duration of the perforation before operation. (3) The injection of the peritoneum. (4) The type of operation performed. He believed primary gastroenterostomy prolonged the operation and added to the primary mortality. Dr. Woolsey brought up the point that apparently gastroenterostomy was curative. This was not so in all cases, as one of Dr. Woolsey's cases was operated on by the speaker for recurrence after a perforated ulcer at the suture line of his gastroenterostomy.

Dr. KELLOGG, in closing, said that the duodenum was not covered by peritoneum. One had to put these sutures in with greater care than in gastroenterostomy, but in his cases there had been no leakage or complications of any kind. As regarded the method of diagnosis by percussion, it seemed difficult and obscure, but in actual practice he had found that one could make the diagnosis in that way and very frequently this had been borne out by the *x*-ray examination and by operation. The important point in his method of diagnosis was that the area of duodenal tympany was increased by deep pressure, while tympany coming from the stomach and colon was diminished. The reason for this was easily understood when one remembered that the duodenum was deeply placed behind the stomach and colon. In a patient with a thin abdominal wall it could be possible to press the hand hard enough to force the gas out of the duodenum and produce tympany, but before reaching that stage one should be able to recognize the increase in the tympanitic note. The other point was upward pressure below the transverse colon, which allows the gas to escape from the duodenum so it could be felt or heard gurgle under the fingers, after which the area of duodenal tympany diminished.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

Austin, June 18, 1918.

ANATOMY.

1. Give size of pancreas and its position in relation to vertebræ.
2. (*a*) What nerves form the cervical plexus? (*b*) What nerves form the brachial plexus?
3. Give location, length and branches of the innominate artery.
4. What joint in the body has the largest articulation? Name its principal ligaments.
5. (*a*) How many bones in the tarsus? (*b*) How many articular surfaces
6. (*a*) What bone in the tarsus has two articular surfaces only? (*b*) What bone has four?
7. Name the ribs that have peculiarities.
8. Give origin of the great sciatic nerve.
9. Draw a diagram of the outer aspect of right innominate bone.
10. Name the five points on the innominate bone which you consider most important.

PHYSIOLOGY.

1. What percentage of the body weight is blood?
2. What is the average time for complete circulation of the blood?
3. What chemical changes take place in the muscle during contraction?
4. Give functions of the pancreatic juice.

5. What part of the brain controls respiration and circulation?
6. Give origin and fate of red corpuscles.
7. Give function of thyroid gland.
8. Give mechanism of respiration.
9. Give ingredients and functions of gastric juice.
10. Give function of cranial nerves.

CHEMISTRY.

1. Difference between physical and chemical change.
2. Give common name and physical properties of $MgSO_4$.
3. Why should we not use pure water through lead pipes? Why may we safely use river water through same pipes?
4. How are oxides formed? Give examples of two common oxides.
5. Give delicate test for albumen in urine. How does specific gravity of urine vary as amount of albumen changes?
6. From what source do we get carbolic acid? How prepared? Physical properties? Antidote?
7. In Fehling's test or any copper sulphate test for sugar in urine describe action of reagents used and if sugar is present, color of deposit? What is the deposit?
8. Complete: $H_2SO_4 + \text{——} = MgSO_4 + H_2O + CO_2$. What is the above reaction called?
9. Name elements of halogen group. Name of three useful halogen salts.
10. Give antidote for caustic potash.

HYGIENE.

1. Name five contagious diseases and give best methods of preventing their spread in a community.
2. Give a brief description of the best method of handling the sewage of a small town without sewerage system.
3. What diseases are often spread by the drinking of impure water and how purify water for drinking?
4. How rid a community of malaria?
5. Name the diseases commonly found in the routine examination of school children.
6. How may typhoid infection occur?
7. Give hygienic treatment of case of chronic interstitial nephritis.
8. Give hygienic care of lobar pneumonia patient.
9. How would you regulate or what measures would you enforce to secure a pure supply of milk from a dairy?
10. Give the hygienic care of early pulmonary tuberculosis.

HISTOLOGY.

1. Describe and tell where each of the following cells is found: (*a*) squamous, (*b*) cuboidal, (*c*) columnar, (*d*) goblet.
2. (*a*) Describe mucous membrane. (*b*) Serous membrane.
3. What kind of tissue is bone? How much organic and inorganic matter in bone?
4. Draw a diagram in full of a neuron.
5. In what veins are valves present and what is the function of these valves?
6. Locate secretory glands of stomach. How do they differ from that of small intestines?
7. How does muscle coat of large intestine differ from that of small intestine?
8. Describe appendices epiploicæ.
9. What kind of gland is the pancreas? Name its duct.
10. (*a*) What is periosteum? (*b*) Endosteum?

ANSWERS.

ANATOMY.

1. The *pancreas* is about 6 to 8 inches in length, 1 to 1½ inches in depth, and from ½ to ¾ inch in thickness. It lies in front of the first and second lumbar vertebræ.
2. The *cervical plexus* is formed by the anterior primary divisions of the first three and part of the fourth cervical nerves.

The *brachial plexus* is formed by the anterior primary divisions of the fifth, sixth, seventh, and eighth cervical, and the greater part of the first dorsal nerves.

3. The *innominate artery* arises from the upper aspect of the arch of the aorta, a little above the level of the upper border of the second right costal cartilage, and it terminates behind the upper border of the right sterno-clavicular articulation.

It is from 1½ to 2 inches in length.

It divides into the right common carotid and right subclavian arteries. As a rule, it gives off no branches in its course; occasionally, however, it gives off the thyreoidea ima artery.

4. The joint having the largest articulating surfaces is the knee-joint.

The *ligaments of the knee-joint* are: Anterior, posterior, external lateral, internal lateral, capsular, anterior or external crucial, posterior or internal crucial, transverse, coronary, and two semilunar fibro-cartilages.

5 and 6. The *tarsus* consists of seven bones.

ARTICULATIONS.—*Os calcis:* Astragalus and cuboid.

Astragalus: Tibia, fibula, os calcis, and scaphoid.

Cuboid: Os calcis, external cuneiform, fourth and fifth metatarsals, and (sometimes) scaphoid.

Scaphoid: Astragalus, three cuneiform, and (sometimes) cuboid.

Internal cuneiform: Scaphoid, middle cuneiform, first and second metatarsals.

Middle cuneiform: Scaphoid, internal and external cuneiform, and second metatarsal.

External cuneiform: Scaphoid, middle cuneiform, cuboid, and second, third, and fourth metatarsals.

7. The ribs that have peculiarities are the first, second, tenth, eleventh, and twelfth.

8. The *great sciatic nerve* arises from the sacral plexus, particularly from the descending branch of the fourth and fifth lumbar, and the first, second, and upper branch of the third sacral nerves.

9. See any standard text-book on Anatomy.

10. *Five important points on the innominate bone:* Crest of the ilium, acetabulum, anterior superior spine of ilium, symphysis pubis, and tuberosity of the ischium.

PHYSIOLOGY.

1. The amount of blood in the body was formerly estimated at about one-thirteenth (say 7 per cent.) of the body weight. More recently it has been estimated at about one-twentieth (5 per cent.) of the body weight.

2. The average time for complete circulation of the blood is a little less than half a minute (about twenty-five to twenty-seven seconds); it is often said to correspond with the time of twenty-seven heartbeats.

3. The *chemical changes which occur in a muscle during contraction* are: (1) It consumes more oxygen: (2) it sets free carbon dioxide; (3) it produces sarcolactic acid; (4) it becomes acid in reaction; (5) it produces heat; (6) it loses glycogen.

4. *Functions of the pancreatic juice:* (1) It changes proteids into proteoses and peptones, and afterward into polypeptides and amino-acids; (2) it converts starch into maltose; (3) it emulsifies and saponifies fats; (4) it causes milk to curdle.

5. Respiration and circulation are controlled by nerves which arise from the gray matter in the lowest part of the floor of the fourth ventricle of the brain (calamus scriptorius).

6. In embryonic life the red blood cells are formed in the area vasculosa. Later on they are formed in the pulp of the spleen; in postnatal life they are formed in the red marrow of bone. They are broken down in the liver and spleen, and the hemoglobin aids in the formation of bile pigments and the pigment of the hair, skin, etc.

7. The *function of the thyroid* is not definitely settled: (1) It has some trophic function regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances; and (3) it produces an internal secretion.

8. "Respiration is carried on under ordinary circumstances by the diaphragm and external intercostals enlarging the chest and sucking air into the lungs, fol-

lowed almost immediately by the recoil of the elastic lungs and ribs forcing out the air so inspired. But when there is a more than ordinary venous condition of blood in the system greater efforts must be made to supply the lungs with oxygen, and muscles not ordinarily employed in the effort must be brought into play. The arms and scapulæ are fixed by seizing hold of some object, and by bringing into action the trapezius, levator anguli scapulæ, and rhomboidei, so as to make firm attachments for serratus magnus, pectorales and latissimus in their efforts to raise the ribs. Labored expiration in like manner brings extra muscles into play. In labored respiration the nostrils are expanded by the dilatores naris during inspiration, and resume their original size during expiration. The glottis is widely open during inspiration, while it is narrowed during expiration. These movements of the glottis occur during ordinary breathing, but are exaggerated during difficult breathing.

"Breathing is a reflex act, capable of being modified by the will. The nerve-center is situated in the medulla, the *afferent* nerves are the vagi; the *efferent* nerves are the phrenics, intercostals, etc. Respiration continues in the absence of consciousness and after the removal of the brain about the medulla; but destruction of a certain small portion of the medulla below the vasomotor center causes the movements at once to cease. This spot is called *nœud vital*. The center is influenced by impulses from without or within—a dash of cold water in the face, a cold bath, an emotion, venous blood in the pulmonary vessels, all call it into action. The center is probably automatic as well as reflex, section of the vagi, thereby interrupting the channel by which the afferent impulses reach it from the lungs, while interfering with the respiratory act does not stop its action. Automatic impulses descend from the center along the efferent nerves. Probably the venous blood circulating through the center itself supplies the stimulus."—(Ashby's *Physiology.*)

9. *Gastric juice* is a thin, colorless fluid; acid in reaction; specific gravity about 1002 to 1010; and containing about 1 per cent. of solids. It contains: Water, pepsin, rennin, hydrochloric acid, chlorides (of calcium, sodium, and potassium), and phosphates (of calcium, magnesium, and iron). Its action is to change proteids into proteoses and peptones, and to curdle the casein of milk; it is also slightly antiseptic, and inverts cane sugar into dextrose and levulose.

10. The special *names* by which the twelve pairs of nerves are generally known are: (1) Olfactory; (2) Optic; (3) Motor oculi; (4) Trochlear or Pathetic; (5) Trifacial; (6) Abducens; (7) Facial; (8) Auditory; (9 Glossopharyngeal; (10) Pneumogastric or Vagus; (11) Spinal Accessory; (12) Hypoglossal.

Functions: (1) Special sense of smell; (2) Special sense of sight; (3) Motor; (4) Motor; (5) General sensation and motor; (6) Motor; (7) Motor; (8) Special sense of hearing; (9) General sensation and special sense of taste; (10) Motor and general sensation; (11) Motor; (12) Motor.

CHEMISTRY.

1. A *physical change* is such a change as does not alter the composition of a substance; a *chemical change* does alter its composition.

2. The common name of $MgSO_4$ is Epsom salt; it is a crystalline solid, is easily soluble in water and the solution is neutral to litmus paper; it is insoluble in alcohol; the crystals are colorless and transparent.

3. "Lead in drinking water has been a prolific source of chronic lead poisoning. As lead is only dissolved by water after oxidation, conditions favoring oxidation of the metal favor its solution. Such conditions are: The presence of nitrates, a highly aërated condition of the water, alternate wetting and drying of the surface of the metal, the absence of sulphates and carbonates, and the presence of much carbonic acid dissolved under pressure (soda water). Sulphates and carbonates prevent solution by the formation of a protecting coating of an insoluble salt. As a rule, the purer the water the more liable it is to dissolve lead when brought in contact with that metal, especially if the contact occur when the water is at a high temperature, or when it lasts for a long period."—(Witthaus' *Manual of Chemistry.*)

4. *Oxides are formed:* (1) By heating the metal in air; *e.g.* zinc oxide. (2) By heating certain salts; *e.g.* calcium oxide (prepared by heating calcium carbonate).

Two common oxides: Sulphur dioxide, and manganese dioxide.

5. *Test for albumin in the urine:* "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture and again filtered. The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid and heated. If albumin be present a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

The specific gravity generally varies inversely with the amount of urine excreted, and directly with the amount of solids contained. A low specific gravity generally indicates albumin.

6. Carbolic acid is obtained from coal tar, or gas tar; it is also prepared by heating salicylic acid and quicklime; it is also obtained by synthesis from acetylene.

Carbolic acid crystallizes in long, colorless needles, has a characteristic odor, and an acrid burning taste, is soluble in 15 parts of water, and is very soluble in alcohol and in ether; it is neutral in reaction.

The *antidote* is alcohol, or sodium sulphate.

7. The copper tests for sugar in urine depend upon the fact that in strongly alkaline solutions glucose reduces cupric hydrate to cuprous hydrate (yellow color) or cuprous oxide (red color).

8. $H_2SO_4 + MgCO_3 = MgSO_4 + H_2O + CO_2$.

9. *Elements of the halogen group:* Fluorine, chlorine, bromine, and iodine.

Three useful halogen salts: Sodium chloride, potassium iodide, potassium bromide.

10. *Antidote for caustic potash* is a weak acid or vinegar.

HYGIENE.

1. *Five communicable diseases:* Smallpox, whooping cough, diphtheria, typhoid, and acute anterior poliomyelitis.

Smallpox may be prevented from spreading by compulsory vaccination and prompt isolation of all cases.

Whooping cough may be prevented from spreading by isolation of all who have been exposed to infection; the patient must avoid contact with others; vaccines have been used.

Diphtheria may be prevented from spreading by isolation of cases and carriers, by the injection of diphtheria antitoxin, disinfection of mouth and nose discharges and of toys, cups, spoons, etc., used by the patient.

To prevent the spread of *typhoid fever:* Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food.

Anterior poliomyelitis should be handled by isolation, cleanliness, and destruction of insects of all kinds; special attention must be paid to the discharges from the nose and mouth.

2. Where there is no sewerage system, a properly built privy must be used. *A sanitary rural privy* consists of a "small watertight pit, not drained but roofed over to exclude rain, and so arranged that the excreta and ashes become thoroughly mixed. For this purpose either the ashes must be thrown in through the closet seat, which may be hinged so as to be lifted *en masse*, or else a 'shoot' or sloping slab must conduct one and the other to a common point. The floor should be smooth, and raised a few inches above the ground level.

"The contents ought to be removed at fixed short intervals, and the work should be done at night or early in the morning so as to minimize the nuisance."—(Whitlegge and Newman.)

Privies and cesspools must be properly protected and the contents buried with chloride of lime, not less than two feet deep; later on it is used as a fertilizer. Garbage may be burnt, after edible matter has been used as food for pigs.

3. *Diseases which may be spread by the drinking of impure water:* Typhoid, cholera, dysentery, diarrhea, goiter, lead poisoning, and intestinal worms.

The means of purification of public water supplies are storage and sedimentation, chemical treatment, and filtration. *Sedimentation.* A part of the impurities in the water may be removed therefrom by storing the water in basins where the suspended matter sinks by the action of gravity, and in the process of settling entangles other impurities, as well as some of the bacteria in the water. In order to get good results, the basins must be shallow, the water left undisturbed and the accumulated sediment removed from time to time. No complete reliance can be put on this method, as it does not guarantee a germ-free water. *Chemical purification:* The sedimentation of water in the basins may be hastened by the addition to the water of certain chemicals, which act as coagulants and form precipitates, entangling the organic impurities and bacteria, thus freeing the water from a large part of them. Alum (half a grain to the gallon), chlorine, bromine, copper sulphate, metallic iron, and ozone are used for this purpose. Neither sedimentation nor chemical purification are practicable for large water supplies, nor are they free from many objections. *Filtration:* This is the only method which has proved successful in providing a pure water supply. Filtration of large quantities of water is accomplished by means of sand beds of large area the sides and bottoms of which are concreted, and on the bottom of which are placed numerous perforated and open drains which are to lead off the filtered water into separate special reservoirs. On the bottom of the filter areas, which are usually half or an acre in size, is placed a layer of coarse gravel, upon this a layer of finer gravel, which is then covered by a layer of fine, sharp sand, several feet in thickness, the whole filtering medium being from four to six feet in thickness. The filter is at first filled from beneath so that all air is driven off, and the filter area is then filled to a level of several feet above the filter bed. A filter of an acre in area may be made to filter two to four millions of gallons of water in twenty-four hours. Such filters act not only mechanically in intercepting all suspended impurities, but the slimy sheet which soon covers the top layer of the sand acts biologically upon the water and destroys a large number of bacteria, so that, it is claimed, the water may be freed from 99 per cent. of its bacteria, provided the rate of filtration is not too rapid and the top of the sand-layers is scraped off half an inch from the surface from time to time.—(From Price's *Essentials of Hygiene.*)

4. *Prophylaxis of malaria:* Individuals should use mosquito netting around their beds and wire gauze in doors and windows so as to keep out the mosquitos as much as possible. During residence in malarial districts quinine should be taken every morning, before breakfast. All pools, stagnant water, etc., where *anopheles* may breed, should be removed. All mosquitos, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is also beneficial.

5. *Diseases commonly found in the routine examination of school children:* Adenoids chorea, myopia, pediculosis, ringworm, imperfect hearing, enlarged tonsils, carious teeth, scabies.

6. *Typhoid fever* is caused by the *Bacillus typhosus.* It enters the body by the mouth, and is conveyed by food, fingers, flies, fomites, and carriers.

7. *Hygienic treatment of chronic interstitial nephritis:* The patient "must be cautioned not to expose himself to the inclemencies of the weather, to avoid all excessive muscular exercise, and all mental worry; he must have his bowels open at least once daily (alkaline mineral waters, saline cathartics, occasional blue mass pill, etc.); and he must favor the action of the skin so as to relieve the subnormal cardiovascular-renal system; warm or hot baths are serviceable, but they are contraindicated if they cause unpleasant throbbings (increasing blood pressure). The diet is of the utmost importance, the duration of life probably depending more upon discretion in eating and drinking than upon any other factor. In many cases an exclusive milk diet for a time (four to six weeks) is desirable; and it may be repeated from time to time. In general the diet should be sufficiently varied to be attractive; it should be free from irritating qualities and readily assimilable, and the nitrogenous constituents should be relatively reduced. The meat allowance should not exceed 100 grams daily; a diet of ample fuel value should be constructed by adding a sufficiency of fats and carbohydrates; an excess of meat is said to favor the development of uremia; red and white meats are of equal value, and may be allowed in accordance with the patient's desires. As a rule, alcohol should be prohibited, although in some cases a little of the lighter wines appears to do no harm. In many cases the foregoing produces not only amelioration of the symptoms, but perhaps also arrest of the lesions; if so, other measures are not required."—(Kelly's *Practice of Medicine.*)

8. *Hygienic treatment of lobar pneumonia:* "The patient should be placed in a large, readily ventilated room, and the windows should be kept wide open all the time, so as to provide an abundance of fresh air. When available, as in hospital practice, the best results are achieved by placing the patient out-of-doors, as on a porch, for instance; he should, of course, be well protected by a sufficiency of bedclothes. The fresh air tends to promote an efficient aeration of the blood, it lessens the cyanosis, invigorates the cardiovascular system, reduces the general intoxication, etc. There can be no comparison between the results attained by affording the patient from the beginning an abundant supply of fresh air, and those that ensue upon the giving of canned oxygen when cyanosis has become extreme and the patient's vitality has been almost if not quite depleted by the intoxication."—(Kelly's *Practice of Medicine.*)

9. *Hygienic management of tuberculosis:* "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammonck or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

10. *Essentials for the production and preservation of pure dairy milk:* Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day to prevent bad odors. The can should remain uncov-

ered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° Fahr., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer it must be kept in a clean place, and at a temperature some degrees below 60° Fahr."

HISTOLOGY.

1. *Squamous cells* are flat, nucleated, epithelial cells, cemented together at their edges, and occurring in a single layer. They are found lining the vascular system, pleuræ, pericardium, peritoneum, bursæ, and synovial sacs.

Columnar cells are tall, cylindrical, nucleated, epithelial cells, occurring in a single layer. They are found in the mucous membrane lining the stomach, intestine, bronchi, urethra, gall bladder, and the ducts of most of the secreting glands.

Cuboidal cells are similar to columnar cells, but the cells are shorter. They are found in the thyroid, testis, and some other glands.

Goblet cells are cylindrical cells distended with mucin; they are a modification of the columnar cells, and are found in the stomach, intestines, trachea, bronchial tubes, and mucus-secreting glands.

2. *Mucous membrane* consists of a superficial layer of epithelium which is supported by a basement membrane, which latter rests on connective tissues or corium. The basement membrane is supplied with bloodvessels, lymphatics, and nerves. Mucous membranes contain secreting cells and are continuous with the surface of the body.

Serous membranes are closed sacs which line the great cavities of the body. They consist of a mesothelial lining which rests upon areolar connective tissue containing capillaries and lymphatics. The mesothelium consists of large, flat, epithelial cells, with occasional stomata between them.

3. Bone is a specialized form of connective tissue.

The organic matter forms about one-third, the inorganic matter about two-thirds.

4. A *neuron* is a nerve cell with all its processes. The cells vary in size, but are generally large. They have one or more processes, a distinct nucleus, but no cell wall; the nucleus has a nucleolus; the cytoplasm is pigmented. The processes are the axis cylinder or axone, collaterals, and dendrites. The *axone* is usually a long protoplasmic process which carries an impulse away from the cell. It may be covered with a medullary sheath and a neurilemma. The function of the neuron (cell) is to receive or send out impulses, and to nourish the processes.

5. Valves are found in most of the larger veins, particularly in the veins of the extremities. They are lacking in the venæ cavæ, the hepatic, renal, pulmonary, portal, uterine, umbilical, and cerebral and meningeal veins.

Their function is to assist the flow of blood to the heart against the influence of the force of gravity, and to prevent the flow of blood in the opposite direction.

6. The *secretory glands of the stomach* are distributed throughout the entire fundus and body, and sometimes at the pylorus. (They are known as peptic, parietal, fundus, or oxyntic glands.) There are also pyloric and cardiac glands which secrete mucus; and are located at the pyloric and esophageal orifices, respectively.

The *small intestine* has Brunner's glands, Lieberkuehn's glands, and the solitary glands (Peyer's patches); these last are not true secretory glands. Brunner's glands are compound racemose glands situated in the submucous coat, with their ducts piercing the mucous coat; they are only found in the duodenum. *Lieberkuehn's glands* are simple tubular glands with a basement membrane supporting columnar epithelium; a few goblet cells are also present.

7. The muscle coat of the large intestine differs from that of the small intestine: In that the outer longitudinal coat is arranged in three flat, longitudinal bands, which cause a sacculation of the large intestine.

8. The *appendices epiploicæ* are peritoneal pouches containing fat, attached to the outer coat of the large intestine.

9. The pancreas is a compound tubular gland. Its duct is named the Duct of Wirsung.

10. *Periosteum* is a fibrous connective tissue membrane, firmly attached to the surfaces of bones except at their articular surfaces.

Endosteum is a membrane which lines the marrow cavity of bones.

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	S. W. Welch, Montgomery	Montgomery	July 8
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix	Phoenix	April 1
Arkansas	T. J. Stout, Brinkley	Little Rock	May 13
California	C. B. Pinkham, Sacramento	Los Angeles	Mar. 17
Colorado	David A. Strickler, Empire Building, Denver	Denver	April 2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Mar. 11
Delaware	J. H. Wilson, Dover	Wilmington	Jan. 17
Dist. of Col'bia	E. P. Copeland, Washington	Washington	April 8
Florida*	W. M. Rowlett, Tampa		
Georgia	C. T. Nolan, Marietta	Atlanta	
Idaho*	Ray H. Fisher, Rigby	Pocatello	April 1
Illinois	F. C. Dodds, Springfield	Chicago	Mar. 3
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Feb. 26
Iowa	G. H. Sumner, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	Feb. 11
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. W. Mahler, New Orleans	New Orleans	
Maine	F. W. Searle, Portland	Portland	Mar. 11
Maryland	J. McP. Scott, Hagerstown	Baltimore	
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston	Mar. 11
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 10
Minnesota	T. McDavitt, St. Paul	Minneapolis	April 1
Mississippi	J. D. Gilleylen, Jackson	Jackson	
Missouri	G. H. Jones, Jefferson City	St. Louis

CANCER: GENERAL MECHANICAL PRINCIPLES.

BY FINLEY R. COOK, M.D.

NEW YORK.

THE greatest need to-day in the treatment of cancer, is a rational working hypothesis.

In the exclusive radio-treatment of the malignant process, with either radium or the *x*-rays, it is apparent that the sole objective is purely local, and is based upon the assumption that the final issue is solely dependent upon the adaptation of dosage to the various specific anatomical and pathological variations, which characterize its localized dynamic manifestations through structure.

This current viewpoint, which completely ignores all general biophysical and biochemical potentialities, necessarily involved in all transmutations of potential to dynamic, pertaining to the phenomenon as a whole, is undoubtedly the natural heritage of the ultrasurgical era; which not infrequently culminated, just as in the case of excessive and exclusive radiations, in futile or deprecable tissue destruction, both normal and abnormal; and the acceleration of metastatic dispersions.

However consistent it may be, therefore, from this limited perspective and its correlated irrational mechanic conceptive, to concentrate all efforts toward the attainment of precision with respect to merely local radio-adaptations, the only prospects in the exclusive pursuance of this routine are wholly dependent upon some radical and apparently chimerical innovation in local technique.

Granting that more cases have responded to what has erroneously been interpreted as the purely local effects of radiations, if only in sporadic and selected instances, cumulative experience is amply demonstrating the glaring impotency of all so-called local and specific interventions; and while it is only too obvious, from a general survey of the situation, that there is something radically wrong with the common concept of the disease, and consequently with the treatment of the same, and that absolute empiricism must eventually give way to progressive rationalism, in cancer as well as in general therapy, there are numerous specific facts and general basic principles which not only reveal the flagrant sources of gross inefficiency, but coincidently the pressing need of a much broader point of view.

The exigency for a more comprehensive viewpoint is more vividly realized when consideration is given to the self-evident fact (irrespective of the basic principles of equilibration which pertain to all biomechanical phenomena, manifest alike in either natural normal growth or natural, however abnormal, over-growth) that if the absolute removal or destruction of its localized effects were universally —and furthermore, even permanently—successful the cancer problem, the essence of which is prevention rather than remediation, through the removal of causes, whether primary or secondary, would still remain unsolved.

In the first place the local concept of the origin, nature, and treatment of cancer completely ignores the basic principles of general biology. From every biological viewpoint—biohistological, biophysiological, biophysical, or biochemical—there would appear to be no evidence that cancer or any other so-called local disease is absolutely dissociated, uncorrelated, or incoordinated, as regards the adaptations of the organism as a whole to its environment or the multitudinous interadaptations relevant to the whole and its cell-unit parts; for in virtue of the histological and physiological differentiation of the organism, from germ-cell unity to variation, through ontogenetic evolution, a reciprocal and metabolic interaction, coordinative as well as differentiative, is necessarily maintained between all structural and functional variations.

Furthermore, it is clinically demonstrable that local changes in structure and function involve changes in general temperature, pulse-rate, osmosis, blood-pressure, and hence in general metabolism; and that such general changes induce, in turn, other local changes in structure and function, with an illusively localized aspect.

All efforts to draw precise and consequently immobile lines of demarkation between general and local, organic and functional, normal and abnormal variations are evidently traceable to a seemingly deeply rooted pathological illusion, based upon a purely static viewpoint of biomechanical motions in general.

This static viewpoint, therefore, must necessarily retard all biological progress; for a mechanical basis, which is everywhere conceded to be the final and only real objective of general biology, involves the principles of dynamics as well as of statics, and no sharp lines of demarkation ever have or obviously can be drawn between the two.

As pathological states could introduce no principles or laws, save those which pertain to normal states, the various biological phenomena through which they are made manifest, such as heredity and environment, soma and germ-cell, endosmosis and exosmosis, assimilation and elimination, alkalinity and acidity, enzymotic syntheses and analyses, electronic associations and dissociations, anabolism and

catabolism, etc., and their respective interactive adaptations, must constitute fundamental factors in all malignant transmutations; and, furthermore, it is only too obvious how the most distinctive features of the cancer cell, viz., hypo-growth and hyper-reproduction, reveal some mechanical change in the polarity, or normal interactive relativity between two complementary and basic biological phenomena: the somatic and germ-cell cycles.

In the second place, the local viewpoint of cancer entirely ignores the principles of general biological evolution. The vast majority of scientists to-day voice the opinion that evolution has been firmly and unquestionably established as the universal law which governs all biological transmutation; and by some regarded as of even greater import than the universal laws of gravitation.

Medicine, beyond the domain of normal biology, has paid little if any respect to the evolutionary hypothesis; and the fact that medicine is the most backward of all the various branches of general science may be referable, in part, to the lack of their mutual coordination and the hesitancy of medicine to adopt an evolutionary basis.

If evolution is the law of universal change, then every branch of science, inclusive of pathology, must constitute, as it were, just one differentiated viewpoint of universal evolution.

When consideration is given to the things which medicine and evolution hold in common (for they both revolve around the protoplasmic cell as a common centre; are governed by the same principles of physics, chemistry, statics, and dynamics; and hence are mechanically and fundamentally the same), the gap which separates them is all the more surprising. Neither is it reasonable to assume that the insidious transmutations from normality to abnormality are concomitant with the mysterious evaporations of the universal forces and laws which obtain under normal conditions; and there is ready evidence, particularly so in cancer, of a gradual and insidious change from slightly abnormal or benign states, through various degrees of malignant progression, and the insidiousness of the transmutation is so typically evolutionary in character as to give rise to the three classic interpretations: positive, negative, and reciprocal, depending upon the spatial point of view.

There are, however, ample reasons for the incoordination of internal medicine and evolution; and while some are traceable to medical and others to evolutionary sources, in reality they are common to both; and the most important pertain to the nature of laws in general, through which not only biological laws, but the simple physical phenomena which underlie them, have been interpreted.

The axiom that all general laws, in virtue of their double meaning, overreach their mark would seem to strike directly at the heart of the whole situation.

In both fields of research, futile efforts are still being made to solve problems in the false concepts of entities, rather in the terms of general laws; in one, it is a malignant entity in the general sense of the word; and in the other, it is the heredity entity, in positive or negative Weismannistic points of view.

The first important laws were those pertaining to universal gravitation, the discovery of which by Newton marked the birth of modern science; and gravity was interpreted as a universal attractive or centripetal force.

If gravitation is a universal force, it necessarily constitutes one of the fundamental forces in universal intracellular transmutation.

The round form which characterizes embryonicity—cocci, spores, nuclei, and nucleoli—shows the relative dominance of a centripetal over a centrifugal force; the oblong form pertaining to maturity—stratifications, adhesions, chromatin bodies, bacilli, and spirilla, etc.—shows the relative dominance of a centrifugal over a centripetal force, in obligatory actions, reactions, and interactions.

Newton was unable to explain the laws of the so-called gravity force, and the problem has been relegated to some obscure or mysterious property of space. A precisely similar situation prevails to-day in regard to universal evolution; for no two evolutionists have or can agree upon its explanation; and the various versions, whether disguised under the names of Realism and Idealism, Mechanism and Vitalism, Darwinism and Lamarkism, Weismannism and Mendelism, have this in common: they all postulate two differentiated although co-ordinated factors, in actions and reactions, and mention no reciprocal interactive factor to coordinate the former two.

The most recent opinion upon the causes or forces of evolution is that of Osborn, an adherent of no particular school, who, in the "Origin and Evolution of Life," maintains that no real advancement has been made in the past one hundred years or more; that it is best to make a frank confession of failure, to make a fresh start, and to approach causality along lines radically different from those of the past and present. Believing that the whole difficulty arises from the habit of thinking from matter backward into energy, he proposes a reversion to one of thinking from energy forward into matter, and places special stress upon interactive phenomena.

While it is apparently unquestionable that the laws of gravitation, like the laws of normal evolution, remain concealed, it is also apparent that the same situation necessarily prevails in the domain of abnormal evolution; and that the solution of the problem of cancer, in common with all other types of malignancy, is only a part of the mystery as a whole pertaining to universal gravitation and universal evolution. The first general laws of science were the physical laws of motion governing the actions, reactions, and interactions of the sun, moon, and earth; and a problem arose which was called the famous problem of three bodies; and this, like the laws of gravitation and evolution, has remained unsolved.

Newton, however, induced the law of actions and reactions, which were found to be equal and in opposite directions; and the three bodies were shown not to move in completed cycles, but in the incompleted cycles which characterize a continuous spiral movement through rotations and revolutions.

There are three simple principles in general mechanics—positivity, negativity, and reciprocality; the same three principles obtain in mathematics, which constitutes a branch of mechanics, and are

expressed in the three postulates of mind—feeling, knowing and acting, and in the three basic factors of universal knowledge—matter, energy, and ether.

The most notable discussion in the whole history of science was that between Weismann, a Neo-Darwinian, and Spencer, a Neo-Lamarkian, on the relative evolutionary import of heredity and environment, or structure and function. In its simplest terms the question was: is a thing what it is in virtue of what it does; or does a thing do what it does in virtue of what it is? After years of the most vehement disputation, in which when either disputant advanced a positive proposition it was completely negatived by his opponent, the general scientific concensus of opinion was that both champions came off the field equally victorious.

Anatomically, the cerebrum is spheroidal in outline; it is divided into two hemispheres; and the brain mass is composed of cells, also more or less spheroidal in contour.

Mechanically, any mass of such a form, pertaining to its component parts, could be reproduced only by centripetal and centrifugal forces in reversible positive and negative actions and reactions through reciprocal interactions in versions and reversions.

Physiologically, it has been demonstrated that man has habituated himself to function with only one of his hemispheres, although the mechanical nature of the connecting fibers show a structural interrelationship admirably adapted to interactive or reversional functioning, and hence, he has not yet been trained to reverse his points of view. For example, there is an axiom that two and two make four; but behind the illusive exactness of the mathematic proposition is the false assumption that there is in nature such a thing as two and two; to say nothing of four. From one viewpoint, it is positively four; from the opposite one, it is negatively four; and from a reciprocal one, it is relatively + or —, depending upon versions and reversions respectively. Again, it is held that the earth rotates from West to East, and toward the sun; but it is equally true that this is false, and that the earth, as a whole, rotates from East to West, and away from the sun. A, with a microscopic view of a sphere in motion, views a movement from him, and positives a centrifugal force; B, facing directly about, views the movement toward him, hence he negatives B, and positives a centripetal force; C, with a broader and an interactive viewpoint, with respect to both A and B, positives and negatives both A and B reciprocally; for he perceives the sphere as a whole in action.

Bacon is generally accredited with having permanently established science upon a purely inductive basis; and induction functions from specific facts to general laws and principles. As facts, *per se*, however, are devoid of any meaning, when stripped of their multitudinous differentiative and coordinated bearings, their final orientation is effected only through the employment of two mechanical movements in space, mutually opposed; and if the one, which differentiates, is analysis, then its complementary one, which coordinates, is synthesis.

From time immemorial men's minds have been recognized as being analytic or synthetic; and wherever, on approaching truth from its opposite points of view, they have come into mutual contact, whether in State or church, science or art, struggling under the illusion that they were moving in straight lines, a difference of opinion has arisen; and the resultant interaction has ebbed to and fro, depending upon the relative dominance of analysis and synthesis respectively.

Analysis, Synthesis, and Orientation.—As it is impossible to analyze the unsynthetized, or reversely, to synthetize the unanalyzed, to tear down that which is not built up, or to rebuild that which is not torn down, subjective analytic and synthetic receptions involve the mechanical principle of reversions as regards their objective dynamic donations.

Analysis is a destructive and differentiative movement from the whole to the parts; and from simplicity in concrete unity to variations in multiplicity; associating and assimilating dissimilarities; and dissociating and eliminating similarities.

Synthesis, on the other hand, is a constructive and coordinative movement from the parts to the whole; and from variations in multiplicity to simplicity in concrete unity; associating and assimilating similarities and dissociating and eliminating dissimilarities.

As analytic procedures are cumulative with respect to variations, multiplicities, and dissimilarities, and synthetic procedures are cumulative with respect to simplicities, unities, and similarities, they are illusively and mutually contradictory in their respective presentations, and they may apparently go on to infinity, disintegrating and reintegrating truth, without reaching any explanatory objective as regards the reality of truth itself. Moreover, had the whole not been dissociated into its component parts, nothing could be known of the parts; and had the parts not been reassociated into the whole, nothing could be known of the whole. Analyses and syntheses are both qualitative and quantitative; but inasmuch as there is no such thing as quality without quantity, or reversely, quantity without quality, they necessarily present opposite viewpoints of some common or reciprocal interactive principle. Furthermore, as quantity is negative, when quality is positive, and reversely, quality is negative when quantity is positive, their respective presentations are mutually reversible with respect to the same interactive principle.

Again, as no two similars are absolutely similar, or reversely, no two dissimilars are absolutely dissimilar, the principle of relativity is involved in their reciprocally interactive principle.

Analytic and synthetic processes involve mathematic presentations, for analysis proceeds by divisions and multiplications and synthesis recedes by subtractions and additions.

To sum up: As structure and function, general or local, normal or malignant, constitute the analytic presentations of biologic phenomena, structure being positive when function is negative, and reversely, function being positive when structure is negative, they demand some third or common interactive principle in their mutual resynthetization.

As there is no such thing as structure without function, or reversely, function without structure, they present opposite and complementary viewpoints of some common or reciprocally interactive

principle. Mechanically, therefore, neither one is the cause of the other, for they constitute reversible active and passive complements of interactive supplements; in the same mechanical sense that the matter content of a steam engine is not the cause of its steam content, and vice versa; nor day the cause of night.

In conclusion, in virtue of the fact that there are only three principles of general mechanics which are applicable to universal movements in analyses and syntheses, they must of a mechanical necessity be applicable to the analysis of general and local growth; from which it may be deduced that there is no such thing as a local growth, normal or malignant, *per se*.

Matter, Energy, and Ether.—The three postulates which constitute the foundation of universal knowledge are matter, energy, and ether.

Nothing is known of matter, save through energy; nothing of energy, save through matter; and nothing at all of ether, save through the actions, reactions, and interactions of both matter and energy.

Nothing is known, therefore, of the matter-energy analyses, as entities *per se*, for their descriptive and illusive presentations through versions and reversions, involve opposite viewpoints of some reciprocal interactive principle called ether.

The real objective of this basic trinity in any explanation of universal, and hence of all biomechanical changes, through structure and function, is a lucid concept of the indestructibility or continuity of motion, through the conservation and transformation of energy.

As matter and energy involve actions, reactions, and interactions, in accordance with the three basic principles of statics and dynamics—positivity, negativity, and reciprocality—their reciprocal interactions demand a third and basic factor in continuity; hence the obligatory postulation of ether.

The obscuration of this purely descriptive trinity, as well as its illusive paradox, is referable to a compounding of terms; for inasmuch as the dissociation of the whole into its component parts is incomplete, it needs to be further analyzed, as all of the parts have not been reassociated into the whole, it needs to be resynthetized; and as the parts have not been equilibrated from part to part, it needs to be orientated, in order to complete the induction of some reciprocal law in continuity through actions, reactions, and interactions.

The matter-ether-energy analysis differentiates three presentations, as regards qualitative and quantitative movements in space and time; of these the first and third exhibit reversible polarities; for when one is either positive or negative the other is reversely so; and the second is reciprocally positive or negative with respect to the first and third.

The analysis of matter differentiates three presentations—form, extension, and mass; with the same interrelationships as those which characterize matter, ether, and energy. The analysis of form differentiates three presentations—the so-called three dimensions of space. The analysis of extension differentiates three presentations, compressibility, flexibility, and elasticity, in which the first and third are reversibly positive and negative and the second reciprocal.

The analysis of mass differentiates three presentations—solids, fluids, and gases; in which fluids are reciprocally interactive with respect to solids and gases.

The analysis is still incomplete, because actions, reactions, and interactions involve energy as well as matter; and as the properties of matter are positive as to space and negative as to time, those of energy, in virtue of their reversion with respect to those of matter, are reversely positive as to time and negative as to space; and consequently, all the various analytic presentations of matter demand a simple parallelism in terms of energy.

In an ultimate analysis, all the various properties of matter and energy are reducible to one simple presentation—centrifugations or movements from some one assumed point in tentative fixation; and in synthesis, being a reversion, these properties are reducible to centripetations, or movements toward the same given point.

In review, a simple mechanical analysis, synthesis, and orientation of the classic Spencer-Weismann debate upon the interactive adaptative relativity pertaining to heredity and environment, or structure and function, brings to the fore the following and seemingly unavoidable conclusions:

(1) Both disputants selecting the same two biologic factors: one postulated heredity as a point in fixation, and environment as a point in motion; and the other just reversing the order; they described similar circles in opposite directions of space.

(2) Mechanically, neither point, either in a state of relative rest or relative motion, is or could be one in absolute fixation.

(3) Both assumed a subjective completion of their respective circles, contrary to the nature of the objective phenomena they were at the most merely describing; and consequently disproved the evolutionary hypothesis *in toto*, the mechanical basis of which is continuity of motion in endless cycles.

(4) The reciprocal interactive principle, common alike to universal mechanic and biomechanic phenomena and their analyses, irrespective of quality or quantity, namely, ionization through positive and negative ions, in versions and reversions; physiologically expressed under the more complex concepts pertaining to metabolism, constructive and destructive, synthetic and analytic, or anabolic and catabolic, the essence of the entire disputation was entirely overlooked; and hence the analyses were unsynthetized and unorientated; for in a resynthesis both circles would have been reversed; and in an orientation, both circles would have been superimposed, thus leading to the discovery of the actual forces engaged, and the mechanic principles which govern them; as universally manifested in temperature, rhythm, pressure, osmosis, and ionization, namely, centripetal and centrifugal in cyclic continuity through versions and reversions.

Universal gravitation, like universal evolution, was induced from specific facts. The two laws governing the velocities of falling bodies in space, and consequently the universal movements of all ions in all space, namely, that they vary directly as the products of the masses, and inversely as the squares of the distance, have always been regarded as more or less inexplicable.

Experimentally, these laws have been proved to

be strictly true only for relatively short distances of space, and the exceptions have been traced to the personal equation, so called, or to unknown factors. The first law of motion, a body at rest remains at rest, etc., is now obsolete in consequence of the revolution in modern physics and chemistry through inductions drawn from radioactive phenomena, which was interactive in their mutual synthetization.

In brief, it is now known that no body remains at rest; on the contrary, is in a constant state of motion, in which positive and negative ions and electrons describe rotatory and revolutory lines of motion, precisely as the celestial bodies, around some reciprocal and interactive line in relative but ever-changing equilibrium; and in the case at least of radioactive, and deductively of all bodies, with centrifugations of positive, negative, and reciprocal forces—the so-called alpha, beta, and gamma rays, which upon meeting with resistance assume other positions in potential, and then centrifugate the same three lines of force, modified only in quality and quantity, or intensity and duration; and the process may thus apparently go on to infinity.

Analysis, synthesis, and orientation of universal gravitation socalled, in the basic terms of the simplest mechanism, not only explain the laws, or rather law, of the same, but coincidently show why they have not and could not be explained from the viewpoint of universal attraction; for in virtue of the fact that a positive mechanic concept of universality involves a negative and reversible complement in specificity, and one of attractivity, repelativity, their respective analyses and syntheses, the reciprocal presentations of which must necessarily be alternately positive and negative, and hence reversible from a common or reciprocal point of view, remain to be orientated, in order to induce some common or reciprocal law in continuity.

As all positive actions in attractions or centripetations involve negative reactions, in opposite directions of space; the postulation of universal gravitation, through the implication of universal stasis, negatives all laws pertaining to the same, in virtue of the fact that the essence of all law is continuity.

As all actions and reactions involve reciprocal interactions, all actions and reactions are reversely positive and negative; then what appears to be an attraction in one position of space, is, at the same time, a repulsion in an opposite position of space. As it is impossible for a thing both to be and not to be what it appears to be at the same time and space, it is not what it appears to be; and it follows then, that there neither is nor could be such a thing as universal gravitation.

To sum up: As a body cannot come down, that is not up; or go up, that is not down; its coming down and its going up constitute two correlated, complementary, and opposite presentations of the same cyclic phenomenon. If this cycle is energized by two component forces—solar and cosmic respectively, then its descendant and ascendant phases are not the resultants of a simple attractive or gravitational force on the one hand, or repellant on the other, but the resultants of the reciprocal interactions between centripetal and centrifugal forces in reversible positive and negative actions and reactions; in which either a positive centripetal dominates a positive centrifugal or reversely so.

In conclusion: every cell-body, normal or malignant, and its component ions and electrons, are subject to the same three mechanic principles, positive, negative, and reciprocal, in virtue of being energized by the same two opposed and complementary forces—solar and cosmic—in intermittent and reversible actions, reactions, and interactions, to and fro, with respect to some given basic line in relative and ever changing equilibrium; and they express their intracellular and extracellular cyclic transmutations, synthetic and analytic, irrespective of quality or quantity, in cyclic continuity through the reciprocal and interactive phenomena, summarized in temperature, rhythm, osmosis, reciprocal potential pressure, weight, and equilibrative ionizations between basic and acid-forming radicles.

Life and Evolution.—If, when giving consideration to the centripetal force, which, for example, centripetates the apple from tree to earth, the viewpoint is reversed, and some consideration be given to the centrifugal force, which centrifugates the said apple from earth to tree, some other and opposing force presents, with apparent and vital interrelationships with life so-called and its so-called evolution.

If the presentations of life are wholly evolutionary in character, there is no such thing as life without evolution; nor reversely, evolution without life; accordingly, these two factors are complementary; and when one is either positive or negative, the other is reversely negative or positive. Inductively, however, there is life without evolution and evolution without life.

The general analysis, synthesis, and orientation of matter, energy, and ether; the rotatory and revolutory character of the electronic forces in the atom; the decadence of radioactive bodies; the growth and decay of celestial bodies; the periodic law of the elements, with the ascending and descending cycles of their volumes and melting points and their reversely positive and negative and reciprocally positive and negative differentiations, through an infinity of chemical or electronic actions, reactions, and interactions; and reversions through mass actions; all establish ample evidence of not only an evolutionary movement without life, but coincidently, its complement, an involution as well. No life without death is a simple induction; mechanically then, the presentations of life and death are complementary; and hence reversely positive and negative. As death is recessive or negative when life is dominant or positive, then reversely, death is dominant or positive, when life is recessive or negative.

Unicellular organisms demonstrate not only an indefinite life without death, but reversely, an indefinite death without life; those types that are positive to Gram's test, in life, are negative in death; and reversely, those that are negative in life, are positive in death; consequently, there is no such thing as life *per se*, or death *per se*, either as dissociable entities or general principles; for their versional and reversional presentations, however illusively or mutually contradictory, demonstrate the reality of a single and reciprocal law in continuity. The perplexities and illusions which

naturally arise from efforts to induce general principles from such complex analyses as vegetable, mineral, and animal; heredity, adaptation, and environment; growth, metabolism, and reproduction; structure, metabolism, and function; health, metabolism, and disease, etc., are readily and simply clarified when reduced to their mechanic and basic terms; for from a simple mechanical viewpoint, they invariably disclose but one law, with three corollaries, viz., positivity, reciprocality, and negativity; in which when the first series of each group are positive or negative, the third are reversely negative and positive; and the second are reciprocally positive and negative with respect to the first and third.

For example: there is no such thing as heredity without environment, or reversely, environment without heredity; for every specific presentation of heredity is the invariable resultant of an interaction between actions and reactions pertaining to an unbroken continuation of the same general heredity and environment; and reversely, every specific environmental presentation is the resultant of an interaction between similar actions and reactions, pertaining to its heredity and environment; consequently when one is positive in analysis, its complement is negative in synthesis; and vice versa; for their contradictory presentations through versions and reversions, establish an interactive adaptive continuity through positive actions and negative reactions.

The same mechanical principles necessarily hold true with respect to the various properties of life; such as sensation, irritability, and motion; inspiration, respiration, and expiration; secretion, function, and excretion; arterial circulation, and venous; endosmosis, osmosis, and exosmosis; dynamic systolic pressure, reciprocal potential, and dynamic diastolic pressure; anabolism, metabolism, and catabolism; electronic associations, electronic interactions, and electronic dissociations; alkalosis, interactive neutrality, and acidosis; synthetic, reciprocal interactive, and analytic enzymes; hypofunction, equilibrative function, and hyperfunction; vasoconstriction, sympathetic interaction, and vasodilatation, etc., etc., for the first and third series of each group are reversely positive and negative; and the second are reciprocally positive and negative with respect to the first and third.

When mechanically analyzed, synthetized, and orientated, in accordance with the principles of any motion, as revealed in every type of mechanism, from the body falling through space to the reasoning processes of man, they can be demonstrated to be the resultants of the reciprocal interactions of positive centripetal and negative centrifugal; and reversely, positive centrifugal and negative centripetal forces; in actions and reactions; through versions and reversions in cyclic continuity.

That the foregoing induction is a self-evident proposition is obvious, for every phenomenon of change involves motion; and every motion is at the same time, both to and from any assumed and artificially fixed point, in virtue of the three principles of mechanics.

It is therefore a mechanical impossibility for the living cell to inspire, secrete, assimilate, or anabolize, etc., without the relative dominance of a centripetal over its complementary centrifugal force; and reversely, to expire, excrete, eliminate or catabolize, without the relative dominance of a centrifugal over a complementary centripetal force, in interactive and ionic versions and reversions.

Every cell then, living or dead, in relative rest or motion, in common with the elements and their positive and negative electronic motions which energize the same, is the seat of cyclic phenomena.

Mechanically, therefore, it seems to be perfectly clear why neither mechanists nor vitalists have succeeded in establishing a satisfactory explanation of universal normal intracellular transmutations with which universal abnormal intracellular transmutations are necessarily correlated.

(1) Relying entirely upon those branches of science, such as embryology, paleontology, comparative anatomy and physiology, which are merely descriptive in character, interpretatory efforts purported to be explanatory, remained purely descriptive.

(2) As the complex terms of biologic phenomena were not reduced to simple or mechanic terms, what would appear to be the universal design of universal phenomena, namely, "Polarity in Cyclic Continuity," was not completely analyzed and hence impotent as far as a resynthesis and orientation was concerned.

(3) Futile and abortive efforts were made to interpret the somatic or ontogenetic cycle from one point of view; for if its analytic presentations are positive and evolutionary in character; then reversely, its synthetic are negative and involutionary in character; and mechanically, they are necessarily reversible with respect to the first half-phase and the second half-phase respectively.

This seems obvious; for in the first half-phase of the somatic cycle, from germ-cell to mid-life, the synthetic processes of anabolism dominate the analytic of catabolism; a positive centripetal dynamic dominates a positive centrifugal, with an increase in cell potential; centrifugated or expressed in an increase in mass and in an extension in space, differentiated through structure and function, hence negatively involutionary and positively evolutionary in its presentations.

In the second half-phase, from mid-life to death so-called, just the reverse is true, for otherwise the organism would continue to differentiate and to extend indefinitely in space. On the contrary, however, catabolic processes dominate anabolic; analytic, synthetic; centrifugations, centripetations; and involution, evolution.

As the analyses and syntheses of these cyclic phenomena are illusively opposite in directions of space, although correlated through interactions, there could be no such thing as either evolution or involution *per se;* and their equilibration, being interactive, orientates or induces revolutions, in a synthesis from the parts to the whole; rotations, in an analysis from the whole to the parts; and a spiral line of continuity, from part to part.

In conclusion: the one universal mechanical law pertaining to universal biophysical and biochemical intracellular phenomena, is that of "cyclic continuity," universally revealed through "polarity," as regards qualitative and quantitative movements in space and time.

A simple mechanical analysis, synthesis, and orientation of such phenomena, universally manifest through structural and functional variations, in their ultimate and basic terms of matter, energy, and ether, in accordance with the three fundamental principles of general mechanics—positivity, negativity, and reciprocality, show that they are the deducible resultants of the interactions between universal centripetal and centrifugal forces, namely, the universal cosmic pull on the cell and solar bodies and reversely, the universal solar pull on the cell and cosmic bodies in reversible positive and negative actions and reactions through versions and reversions; and consequently should be inducible through universal biophysical and biochemical analyses, syntheses, and orientations.

If these mechanical principles are the universal ones pertaining to all normal transmutations through structure and function; or matter and energy; in virtue of the law of continuity, they are equally applicable to all abnormal, and therefore cancerous transmutations. This concludes the consideration of the general mechanic principles, with evident bearing upon the biomechanic problem of cancer.

The incorporation of these same principles, in what has so far been demonstrated to be a logical approach to a rational working hypothesis, and the application of the same in the treatment of cancer, will appear in a subsequent and complementary article.

40 East Forty-first Street.

THE CLINICAL COURSE AND PROGNOSIS OF THE PNEUMONIAS OF THE RECENT EPIDEMIC.*

By THOMAS F. REILLY, M.D., F.A.C.P.,

NEW YORK.

PROFESSOR OF THE PRACTICE OF MEDICINE, SCHOOL OF MEDICINE, FORDHAM UNIVERSITY.

The pneumonias that have been characteristic of this epidemic have been almost entirely of the catarrhal or bronchopneumonic type. It is unfortunate that we do not have another name for this type of pulmonary affection, because it is so entirely different from ordinary lobar pneumonia. One finds a great difficulty in making the layman understand that this is essentially a different disease from the ordinary pneumonias with which he is acquainted. At the beginning of the epidemic even many physicians could not easily grasp the different clinical picture, although we did have more or less of this bronchopneumonia during the past winter. The relationship of bronchopneumonia and lobar pneumonia might well be considered in the same light as rheumatism and chronic rheumatism —the two are essentially different diseases, although both affect the same tissues somewhat similarly. The confusion of names makes for much misunderstanding in both diseases.

In this epidemic the catarrhal pneumonia picture presented itself in one of three forms:

1. *The Malignant Type,* the history being that the patient was in perfect health, when he was suddenly stricken with chill, fever, cough, dyspnea, usually vomiting, and increasing cyanosis; death occurring in from 24 to 48 hours of the onset.
2. The patient was taken with the symptoms of a moderately severe influenza, *i.e.,* pains and aches, coryza and cough, and a temperature of 102° or 103°. On the third day there was no cessation, on the other hand the temperature rose somewhat on the fourth day and continued elevated throughout the course of the disease.
3. The patient had suffered from the ordinary influenza, and on the third day, as is common in uncomplicated cases of that disease, the temperature fell to nearly normal and remained there for one or two days, then on the 4th or 5th day a chilliness was experienced, the temperature gradually rose, and signs and symptoms of pneumonia appeared. Latterly this fall and rise has appeared frequently on the 4th and 5th days.

Diagnosis.—As a rule in the fulminating cases the subjective and objective symptoms were so marked that even without physical signs (and they were seldom present) one had no difficulty in pronouncing the disease pneumonia.

In the third class of patients the previous history of influenza, with the period of quiescence following and the secondary rise in temperature usually gave a clue of the condition to be expected, so that the greatest difficulty was in the second group mentioned. Here the early onset was not any more severe than in other cases of influenza but the failure of the temperature to fall before the 5th day called the attention of the practitioner to the fact that he was dealing with pneumonia. If one may except the presence of bloody sputum, this continuance of temperature was often the only sign of much value. It may be mentioned that this bloody sputum did not have the same diagnostic value that it has in lobar pneumonia, because the source of it was often due to the accompanying tracheitis. The patient did not seem any worse on the 4th day. On the other hand, mentally, he was usually bright and making light of his illness, so that unless the practitioner had formulated some such rule in his mind that four days of continued fever in influenza without any other well-defined cause means pneumonia, he was apt to continue the diagnosis of simple influenza through one or two weeks of fever, awaiting the appearance of definite signs of pneumonia. As in most catarrhal pneumonias the physical signs usually were very variable. This must be so because of the varied pathological picture presented in the lungs—a tympanitic percussion note, absent or diminished vocal fremitus, and showers of fine consonating râles, especially noticeable on deep inspiration and more pronounced on one side than on the other. Usually these signs were to be found in the area between the lower angle of the scapula, the base of the lung, and the vertebral column, being more marked on one side than on the other. In many instances there was an entire absence of breathing over these portions of the lungs. When this was present slight dullness could be elicited. In some cases there were present small localized areas of fine râles and when these persisted with fever much significance might

*Read at meeting of Medical Society of the Greater City of New York, December 16, 1918.

be attached to them, so that in early cases one listened for silence or for consonating râles, or both. Later on, of course, one might find slight impairment of resonance—bronchovesicular breathing and sometimes bronchial breathing, but at that time usually anyone could make the diagnosis on the clinical history alone without listening to the chest. A peculiarity about these physical signs was that they might be present on one day and absent on the next. In this respect they resembled the picture of acute miliary tuberculosis. In a general way it may be said that one made the diagnosis early either on the presence of continued fever and a few râles or on the presence of physical signs of consolidation and symptoms. Sometimes the general symptoms were surprisingly slight and only their continuance made one search carefully for signs of a pneumonia. In other words, the diagnosis was made on fever, râles, and symptoms, at least two of the trilogy being present. Of these symptoms the *early cyanosis* was the most striking as well as the most awful. It was unlike the cyanosis of any other acute disease, and the patient looked more like one who was suffering from illuminating gas poisoning than any other of the common disease pictures. The sudden onset, with this cyanosis and fever, often without anything else but a few râles, commonly sufficed for a diagnosis. The disturbed pulse respiration rate had not the same diagnostic value that it has in lobar pneumonia, where a 1 to 3 or 3½ rate is of such great diagnostic importance. Sometimes the respirations were exceedingly slow—16 to the minute—with a temperature of 103° and a pulse of 90. At other times the dyspnea was frightful. Ordinarily, however, the dyspnea bore some relationship to the amount of lung involved and approximated the pulse in a ratio of 1 to 3½. The slow pulse was characteristic of the disease and it commonly continued so until a short time before death and this slow pulse often caused one to forget to compare the respiration rate with pulse. The sputa were red and frothy, but not rusty and did not resemble the sticky sputa of lobar pneumonia.

I was forcibly struck by the frequency of a roughening of the first sound of the heart, from the base down along the left sternal border. This murmur, if such it could be called, was not transmitted and did not grow more marked during the progress of the case. It will be interesting to observe the after results in these cases, because Allbutt has insisted that influenza is one of the frequent causes of aortitis. The cough was frequent and usually distressing. Most of these patients suffered from nausea and vomiting at some period of their illness. The presence of nausea, vomiting, and excruciating pain in the epigastrium and later on in the right side of the abdomen was very strikingly suggestive of *appendix disease* and not a few of them have been operated on in the various clinics. In general, pain was for the most part not experienced over the affected area of the lung, although paresthesia was sometimes experienced there. A burning pain across the infrascapular region that appeared and disappeared was not unfrequent. This burning pain and the presence of tenderness on forcible percussion was of service sometimes in attracting attention to the side involved. The sternal pain was that of the accompanying tracheitis. The epigastric pain was sometimes due to the muscular strain of coughing and vomiting but for the most part was a referred pain from the accompanying diaphragmatic pleurisy. This could be easily determined by looking for the usual points of referred pain in this disease: (1) Tenderness and often pain over the trapezius or in other portions of the neck and chest supplied by the 4th cervical nerve. (2) Tenderness and pain were present over Muzzy's button, situated at the junction of the parasternal line and one drawn from the 10th costal cartilage. Nearly all of the cases showed a trace of albumin in the urine and some hyaline casts. For the most part the patients did not look sick. They often appeared bright, and were anxious to get out of bed and were usually making plans for the near future. This caused many of them to get out of bed with the first fall of temperature. In women the menstrual flow came on ahead of time, and if pregnant they miscarried. Many odd and bizarre symptom groups occurred but they were not nearly so common as in previous epidemics. Among these may be mentioned those who presented the symptoms of stupor, coma, loss of speech, and incontinence of urine, along with the signs of a bronchopneumonia. This made up a picture of cerebrospinal meningitis rather than pneumonia. While these patients were apparently moribund for days at a time, and most of them did die, still not a few recovered from what seemed to be a hopeless condition.

Empyema was conspicuous by its absence. When it was present it always raised the question *whether the antecedent pneumonia was not lobar rather than catarrhal.* The relapsing temperature after a period of normal temperature tempted many to aspirate. The physical signs were often strongly suggestive of *fluid*, but there was always something lacking in the physical findings so that one could not feel certain fluid was present. Sometimes this was because the flatness was too localized or the presence of an occasional râle, the absence of the Grocco sign, or the absence of displacement of the heart when the suspected area was on the left side.

The disease commonly ran on for 8 or 10 days and then came down by *lysis.* The temperature did not become normal for three or four days longer. Of course this was not always the case, and often the temperature ran on practically continuous for two or three weeks and sometimes longer. One of the striking features of this disease was the number of relapses. Patients whose temperature had come down by lysis, and by the 12th or 14th day was near normal, would have a rise again, continuing for from three to six days, then fall, and a similar relapse perhaps would occur. In one case I saw five such relapses. It was seldom that the relapse lasted more than six days. Past experience teaches us that resolution does not occur in bronchopneumonia, ofttimes for many months, and that until this does occur relapses are likely. An interesting clinical observation was made in the wards of Fordham Hospital that the males seemed to have most involvement on the left side, whereas the females showed most signs on the right. Of course, this was probably only a coincidence.

In the fatal cases death occurred: (1) By as-

phyxia and coma; (2) with the symptoms of acute pulmonary edema. This often occurred out of a clear sky in patients otherwise doing fairly well. (3) In a large number, however, death occurred with the *Romberg-Passler Syndrome.*

The abdominal distention, which had previously been a troublesome symptom, now became markedly worse. The patient had then the appearance of profound shock—the pulse became irregular, very rapid, 130 or 140; delirium, hallucinations, and restlessness were added. Sometimes pulse deficit could be made out, *i.e.*, there were more beats at the heart than pulse beats. Stupor and coma followed and *death* then closed the scene. In old people sudden death sometimes occurred. The patient was sometimes up and about when this happened.

Differential Diagnosis.—In the differential diagnosis there was commonly little trouble, because the showers of consonating râles at the base, which were so generally present, ordinarily clinched the diagnosis. I may say in passing that there are two other signs of some value to indicate that the patient is suffering from influenza of the respiratory type, even though he may have some other disease and they may serve in calling attention to an otherwise unnoticed pneumonia; these are:

1. The presence of an *enlargement of the puncta of Steno's duct* with a red hemorrhagic area at the point of opening. So far as I know this is an original observation and is present in 70 per cent. of the patients who are suffering from the respiratory form of influenza. It is commonly present on the first or second day, and sometimes disappears after three or four days, but in other cases is present for two or more weeks. It was not present as frequently in children as in adults. Commonly it was more marked on one side than on the other. In relapsing cases it was present longer than otherwise, and on a few occasions I was able to predict a relapse by its continuance. I am not sure that this is always the case.
2. *Redness of the arch of the palate* with a persistent cough is strongly suggestive of a previous influenzal attack.

The four diseases which occasionally cause trouble in the diagnosis are: (1) typhoid fever, (2) meningitis, (3) appendicitis, (4) tuberculosis.

Among the rarer causes may be mentioned: (1) dengue, and (2) acute miliary tuberculosis.

Of the latter two I did not see a case in the present epidemic. The sudden onset and the presence of coryza and râles were the common signs that served to rule out *typhoid fever.* In doubtful cases the Widal clinched the diagnosis. As for *appendicitis* the presence of a few râles and the absence of leucocytosis were the most convincing proofs that the disease was influenza. The pain was more intense than in ordinary appendicitis. The signs did not develop in rotation as is the custom in the Murphy syndrome so common in acute appendicitis. The frequency of unresolved pneumonias of a month's or more duration makes the differentiation from tuberculosis a real problem, so that given a patient who presented signs of bronchopneumonia of a month's duration with its attendant loss of weight and appetite, and other distressing symptoms, as sweating and cough, one in the past has been prone to regard it as tuberculosis, even though the bacillus was not isolated. In view of the commonness of this form of bronchopneumonia at the present time, it is wiser to regard all of these as influenza rather than tuberculosis until a positive sputum has been obtained. Commonly tuberculosis affects the upper lobes, whereas influenza attacks the lower lobes; yet, in this pandemic we have frequently seen both—the upper lobes on one side and the lower lobes on the other—involved in the same case.

Prognosis.—In no disease has the prognosis been more difficult than in bronchopneumonia, because what really seems like a fulminating case will change over night, whereas, a patient who is apparently doing well may suddenly become moribund.

In general, the mortality was: Below 5 years of age about 15 per cent.; from 5 to 15 years about 5 per cent.; from 20 to 36 years about 30 per cent.

In children under one year it was approximately 50 per cent., and yet there were comparatively few deaths because pneumonia was not so common in children as it was in adults. It was not so common nor so fatal in the aged as it has been in the past. Women had almost double the mortality of men. If the disease was contracted from a patient already suffering from influenzal pneumonia the outlook was worse than otherwise. If the first patient died of the pneumonia the second was likely also to die. When a double pneumonia could be made out the mortality was more than 50 per cent.

Cyanosis occurring early was almost invariably fatal, if marked and occurring before the 8th or 9th day it was generally fatal; it was perhaps the most terrible symptom of the disease.

Extreme prostration occurring early usually betokened death; even when it occurred late recovery was uncommon.

A "don't-care" attitude was of ominous import.

Incontinence of urine and feces usually meant approaching dissolution.

The pulse was of very little value in arriving at a prognosis. As a rule the pulse was quite slow and good until 24 or 48 hours before the end. When the pulse did begin to climb, whether early or late, and continued to do so for more than 24 hours, the patient usually climbed into Kingdom Come.

Extra-Systole and Sinus Arrhythmia did not have any prognostic significance. They were more common after the fall of temperature.

A low pulse pressure always suggested a failing circulation but other signs were quite as valuable.

A low respiration, under 30, carried a good prognosis; when it went to 40 or over recovery was rarer. A steadily climbing respiration rate was as bad as a steady climbing pulse.

As to the antecedent condition, fat people were poor subjects for the disease and the mortality was much higher than in wiry ones. Those with a pale, pasty complexion and with poor vasomotor response seemed to be poorer risks than others.

In my experience cardiacs who had already suffered from symptoms of broken compensation before this illness almost invariably died. Old patients suffering from renal disease usually died.

Those suffering from tuberculosis did not appear

to have the same high mortality that others have noticed.

In women the onset of menstruation during the pneumonia had a bad effect on the course of the disease. If the patient was pregnant the child almost never survived, and the maternal mortality approximated 80 per cent.

No one can give assurance to a patient that a relapse will not occur, because even after the temperature has been normal for several days a fresh outbreak may ensue. It is, however, very uncommon for such a return of the pneumonia after 10 days of normal temperature. In patients who suffered from trophic skin disturbances relapses were more frequent. On the other hand, patients who have had severe and prolonged attacks of this disease will suffer for years from the results, in the shape of repeated attacks of bronchitis and bronchiectasis. This is due to the anatomical results of the pulmonary fibrosis which follows in such cases. They have crippled lungs with areas of emphysema here and there which are aggravated with each fresh attack of bronchitis. One sees many such cases that have been suffering since the last pandemic 30 years ago. They are frequently mistaken for tuberculosis.

37 West Eighty-seventh Street.

A SHORT HISTORICAL SKETCH ON DEATH FROM DROWNING.*

By CHARLES GREENE CUMSTON, M.D.,

GENEVA, SWITZERLAND.

PRIVAT-DOCENT AT THE UNIVERSITY OF GENEVA; A VICE-PRESIDENT OF THE SECTION OF THE HISTORY OF MEDICINE OF THE ROYAL SOCIETY OF MEDICINE OF LONDON; MEMBER OF THE MEDICAL HISTORICAL SOCIETY OF FRANCE, ETC.

The most ancient opinion as to the cause of death from drowning is that which attributes it to a too large quantity of water in the respiratory and digestive tracts. In his commentaries on the anatomical writings of Hippocrates and Galen, Jacques Sylvius in his *Opera medica*, Genevae, 1630, lib. 3, cap. 23, makes the remark that like the latter he was in the habit of dissecting monkeys that he had suffocated under water in order to have the bodies in a good state of preservation, and that in the case of human bodies it is better to choose those that have been drowned, rather than those who have died from strangulation or from some wound or disease, because the structures are in a perfect condition, and by strongly compressing the stomach with the hands the water is expelled.

Waldschmit, in 1687, opposed the opinion that in drowning death resulted from the amount of water swallowed or that by entering the trachea and lungs it interfered with the respiratory junctions. According to this writer it is not the compression of the water on the organs that causes death but the want of air with interrupted respiration and secondly the circulation.

Waldschmit points out that respiration must cease at once because air cannot make its exit from the body of drowned subjects any better than water can enter. Therefore, he states that he has never found a single drop of water in the stomach nor in the chest of those dying from submersion.

In 1704, Becker published a little work with a long title: *Paradoxum medico-legale de submersorum morte sine potu aquæ, aliquot cadaverum sectionibus delectum, et e principiis mechanicis illustratum*, Giessae Hassorum, 1704, in which he maintains Waldschmit's teachings. He, however, adds that constriction of the neck in cases of drowning is so considerable, even after some time has elapsed since the submersion occurred, that it is impossible that water could penetrate the lungs or the intestines and that consequently death should be attributed solely to the cessation of the respiration.

The air contained in the thorax of drowned subjects expands, compresses the blood-vessels, and arrests "the movement of the blood," as he says. Therefore, blood is found in large amount in "the pulmonary cavities of the heart, while the aortic cavities contain hardly any."

In a letter addressed to L. Schroeckius under the date of May 8, 1774, George Detharding, on the treatment of drowning by laryngotomy, does not hesitate to uphold that the generally accepted opinion that the cause of death by drowning is due to the entrance of water into the respiratory and digestive tracts is false and devoid of any reason, although he has only a single personal case to offer in support of his thesis.

But these were glorious days, when an opinion could be supported on very little ground and yet find favor among many of our profession. Detharding is not at all at loss to suggest the true cause of death from submersion and he says that those who die from drowning do so because *they have too much air* and not for the reason that they do not have enough! They draw it in but do not expire. From this it results that the pulmonary vesicle becomes overdistended with air, the bronchi become elongated and the pulmonary vessels compressed.

His conception is that the epiglottis closely closes the glottis and consequently water cannot penetrate into the respiratory tract. Those of you who may have the curiosity to read this letter will find it in the second volume of Haller's *Disput. chirurg.*

Littré was of the opinion that the water which found its way into the lungs and stomach could not cause death because it was in too small a quantity. Pulmonary patients, asthmatics, and hydropic patients have water-logged lungs and yet they live on. This cause of death being eliminated in cases of submersion, one must look elsewhere. Respiration ceases. In all of his experiments, Littré never found that the air became excessively rarified in the lungs of drowned subjects as Becker maintained, and he believes that if the latter writer did not find water in the lungs and stomach of the subjects he examined post-mortem it was because death was not the result of submersion, because only a *living* man submerged in water can swallow.

Littré's paper was published in 1719 and in 1726 Senac's paper appeared. This writer was quite positive in his assertion that drowning persons were unable to swallow water and should they do so it would be in such small amounts that it would do no harm. But Senac believed that the want of air caused faintness and "convulsions of the trachea,

*Being the introductory lecture to the course on the History of Medicine, at the University of Geneva, for the academic year 1918-19.

rupture of the pulmonary vessels and expectoration of blood might be the causes of death."

Cerebral hyperemia results, according to Senac, in compression of the "origins of the nerves" and immediately extinguishes all sensation, so that death by drowning is similar to that from strangulation or to negroes who know how "to throw back their tongues and force the gustative organs under the velum palitinum."

After some experiments, Louis, in 1752, emitted the opinion that so soon as an animal is submerged the thorax remains in the same condition that it was before the animal fell in the water. But the necessity to breathe finally forces the animal to suspend movements of the thorax. By the movement of inspiration, water enters the lungs and forces the air contained outward.

In order to give a foundation to his assertions, Louis drowned several animals in colored liquids and he found their lungs stained the same color as the liquids in which they had been submerged, an experiment, gentlemen, which would do credit to any one of our present enlightened generation. He furthermore made sure that water did not enter the respiratory tract of an animal after death, a point upon which I desire to insist.

Louis' experiments on death from submersion were repeated in the presence of Morand and Bourdelin, a commission appointed by the Royal Academy of Sciences to examine his mémoire, and it would appear from all accounts that they were satisfied with the author's conclusions. But this was not enough for Louis that he should have proved that the entrance of water in the lungs of subjects dead from submersion; he still opposed the contrary opinion upheld of such men as Becker, Detharding, Littré and others and for your further instruction on this subject I would refer you to Littré's *Lettres sur la certitude des signes de la mort, avec des observations et des expériences sur les noyés, Paris,* 1752.

In his "Opuscules on Pathology," which was published at Lausanne in 1755, Haller tells us that he had formerly adhered to Becker's theory as to the mechanism of death from drowning, but that in 1748, having had the opportunity of making an autopsy of a female who had been drowned, he demonstrated to his own satisfaction that the lungs were filled with water, for he expressly says: *Omnibus nempé pulmonis pectorisque partibus integris, presso pulmone, aqua, quae in id viscus penetraverat, per asperam arteriam manifesto regurgitavit.*

He refers to experiments that he undertook at the beginning of 1753 on cats and dogs and of those still more numerous that were made at Gottingen that same year by Evers, one of his pupils, and which all offered the same result, namely, that there was much frothy water in the bronchi. To quote his words: *Aqua erat in pulmone, et ea cum multâ spumâ de asperâ arteriâ animalis expressâ opullulabat.*

As to the cause of death, Haller expresses himself as follows: *Et iis* (experiments) *aliqua non exigui momenti corollaria sequuntur; et primo quidem causa mortis in submersis animalibus ea potissimum videtur, quae ab aqua in pulmonem resorptâ atque anzii animalis ultimis nixubus cum aere asperal arteriæ et pulmonis concussâ, inque spumam agitatâ reperitur, eaque spuma nullâ porrô pectoris dilatatione expandi potest, cum minime se, ut aer, elastica expandat.*

In the appendix to the third volume of his Elements of Physiology, it will be seen that Haller had accepted a different opinion as to the cause of death from submersion because we find the following: *Haec theoria, mortisque ab impenditâ respiratione deducta causa, confirmatur experimento canisqui, submersis sub aquâ, vitalis superest, si, per longum tubulum ex asperâ arteriâ eductum super acquam, ei aeris commeatus reservatur.* In a note appended, Haller says that the name of the author of this ingenious experiment has escaped his memory, but I will tell you that it belongs to Gauteron, who published his research work in the reports of the Société de Montpellier, April 17, 1728.

A professor at Göttingen by the name of Roederer, published some observations on death from drowning in a dissertation entitled: *De suffocatis,* which appeared in 1760. In this opuscule he states that in 1753 he was present at Evers' experiments and he relates the findings of the autopsies of two females who had died from drowning which would seem to confirm the opinion emitted by Louis, Haller, Evers and others. I will quote him: *Os, nares, fauces, asperam arteriam cum bronchiis aqueâ spumâ ita exsuperantes, ut vel faciem conspurearet, et compresso pulmone copiosa efflucret.*

In 1762, the learned and exact Morgagni gave to the world the results of his animal experimentation and he candidly admits that, like Valsalva, he had never had an opportunity of performing an autopsy on a drowned person.

Morgagni states that he invariably found a frothy fluid (humor spumosa) in the trachea and lungs of the submerged animals, but never any water, in the strict sense of the word. He occasionally found a little in the stomach. He never remarked that the epiglottis fell back on the glottis.

In 1767, an accident occurred at Lyons which offered the opportunity to Louis to hotly uphold the opinion he advanced fifteen years previously, namely, that water entered the bronchii in drowned subjects. I refer to the case of death of one Claudine Rouge, and the experts appointed in the case were Faissole and Champeaux. During the same year in which they made their medico-legal examination of Rouge they undertook a series of interesting experiments which confirmed Louis' views.

In 1776, Portal published a work entitled *Observations sur la cause de la mort des noyés, et sur les moyens qu'on emploie pour les ramener à la vie.* He informs us that having autopsied several drowned persons and carried out a number of various experiments on animals submerged in colored water, he found a more or less considerable amount of frothy serosity of the same color as the water in which the animal had been drowned. This would seem to conclusively prove that the water entered the lungs.

In an article which appeared in the *Journal de Physique,* in 1778, Gardane advances the opinion that when animals are submerged they become asphyxiated the instant the last air bubbles leave the lungs, and that in consequence, since the subject died in the act of expiration, and without giving

any sign of inspiration, he believed that if any water entered the lungs this could only occur after the last expirating movement, and that, therefore, the water was not the cause of death.

The true cause of death appeared to Gardane to be the effect of the shock and graded expiration, which, by preventing the flow of blood to the brain, arrested the circulation and heart beats while at the same time it caused respiration to cease. Now, Gardane at the same time stated that he found no pulmonary areas stained black in dogs that he had drowned in water to which ink had been added, so that a commission appointed by the Academy of Sciences of Paris to examine the question repeated the experiments, with the result that it was found that more or less water entered the bronchii in submerged animals.

To confirm his opinion, Gardane drowned several dogs in colored water, and in some he found no trace. In the majority of animals he thought that the edge of the glottis was stained, and that some of the froth in the trachea and bronchii was tinted the same color as the water. However, he was undecided as to whether the water entered during life and suffocated the animal, or if, as he suspected, it did not enter the trachea at the moment of asphyxia. To settle the question, Gardane injected every third day, for a month, about an ounce of pure cold water into the trachea of two rabbits. The animals remained unaffected. The water introduced was always absorbed and never vomited, from which he concluded that it is less the presence and weight of the water in the lungs than the painful sensation produced in the nares and on the glottis, the general shock resulting from submersion, and to the violent convulsions that asphyxia is induced, and is quite independent of the more or less considerable amount of water entering the trachea and bronchi.

At just about this time, Macquer gave his opinion on the cause of death from drowning in his *Dictionnaire de Chimie*, Vol. I, and I shall quote him textually: "Animals who die under water perish by the same death as those dying in gas. In both instances they are in reality drowned, and if the same species of animals resist a little longer in water than in gas this is due to the fact that the pressure of the water being an obstacle to the exit of the air contained in the lungs at the time submersion takes place, this amount of air continues to keep up what life is left until it is entirely suppressed and has become incapable of aiding respiration."

Now let us turn to the *Memoires de la Société royale de Médecine de Paris* for the year 1779, and we will find the results obtained by Varnier, who caused a cat to inhale a large amount of cold water in order to ascertain the effect on the lungs. He found that the respiratory movements, which at first appeared to increase and then decrease, resulted in the complete absorption of the water.

From this the natural outcome was that he formulated the following corollary, namely, that since cold water neither arrested nor suspended respiration, it could be admitted that it is erroneous to suppose that death from drowning is the result of the intromission of water in the lungs, since it does no harm, and is absorbed with great facility.

Walter, who appears to have had the opportunity of examining, post mortem, a considerable number of drowned persons, says in his paper, published in the mémoires of the Royal Academy of Science of Berlin, 1782, that he never found water in the stomach nor froth in the lungs, the latter being greatly distended by air. He likewise found the epiglottis normal and the cerebral vessels greatly dilated with blood as in the case of hanging.

As to the rosy froth found in the lungs of submerged subjects, and which is mistaken for water swallowed, it is simply the natural outcome of an exaggerated pulmonary circulation which results in overdistention and consequent rupture of the arteriolæ, giving exit to a few drops of blood, which become mixed with the gelatinous matter of the bronchial tubes, and thus in turn changes into a reddish froth from the action of the greatly diluted air.

The continued dilatation of the lungs prevents the blood from making its exit from the venous system of the brain. The arteries, and especially the veins, are overfilled, they compress the brain and nerves, and consequently act on the entire system. All this indicates but one thing, namely, *that submerged subjects die of apoplexy.* For this reason, Walter believes that it is not only useless, but dangerous, to blow air, especially heated air, into the lungs, since according to his way of thinking a person falling into the water dies because the lungs are too full of air, from which it results that the pulmonary parenchyma is ruptured.

It would seem that John Hunter attributed the cause of death in drowning to a suspension of the respiration, which of necessity would bring about that of the circulation. Therefore, according to his manner of looking at the condition, it is more important to reestablish the cardiac function than that of the respiration.

In this respect, Hunter resorted to experiments on a dog after having removed the sternum in order to expose the heart and lungs, and he observed that when he ceased the insufflation of air, which he did by introducing the tip of a bellows into the trachea, the heart contracted with less force and less frequently, while the contrary took place when artificial respiration was resorted to.

He repeated this experiment ten times on the same animal, allowing from four to ten minutes interval between the insufflations, and each time he observed that the heart became excessively turgescent with blood whose color was quite as dark in the left cardiac cavities as in the right, which was not the case when insufflation was done.

Hunter considered that the situation of this dog was the same as that of a submerged person, and he points out that death in drowned subjects had been attributed by many to the fact that the blood, from want of air, was no longer in a proper condition to keep up respiration, and that, reaching the brain in a vitiated state, as well as to all parts of the body endowed with life, it was thus capable to act on the nervous system, from which would result cessation of all movement. He says, however, that he is convinced that this opinion is false, and that founding his idea firstly upon the experiments made upon the dog, in whom a considerable column of dark blood, namely, all that contained in

the heart and pulmonary veins, was pushed forward without any ill effects resulting; and secondly, on the return to life of drowned subjects and still-born infants, which should not occur unless the condition of the blood in the brain did not undergo some favorable change.

Hunter believed that the cardiac movements depended more upon the immediate action of the air on the lungs than the effects of the air on the blood, which he regarded as absolutely secondary. He is disposed to accord much to fright which accompanies drowning, and does not doubt that the probability of success in restoring patients depends much on this circumstance.

This really remarkable paper of Hunter can be found in the *Philosophical Transactions*, Vol. 66, for the year 1776, and has for title, "Proposals for the Recovery of Persons Apparently Drowned."

In 1788, the Humane Society of London awarded a gold medal to Dr. Edmond Goodwyn, offered to the author of the best essay on the cause of asphyxia from drowning, strangulation, and "nephritic vapours." In this essay, Goodwyn admits that in drowned subjects the left cavities of the heart, as well as the vessels reaching them, are half filled with blood, while the right cavities and veins are greatly overfilled. The right cavities are still susceptible of contracting and dilating if the body is soon opened after death, while the left ventricle and auricle have, on the contrary, lost all their irritability.

Finally, the essayist demonstrates by exact experiments that by drowning animals in colored fluids water entered the lungs during submersion, but in such small amount that he does not suspect that it contributes to the cause of death. Goodwyn bases his assertions on an experiment already done by Gardane and Varnier, and to which I have previously referred, namely, that if through an incision of the trachea four times as much water is introduced than actually takes place in drowning, these animals appear in the first place to be depressed physically, but after a few hours they become perfectly well again. From this Goodwyn attributes the asphyxia to the exclusion of air to the lungs by water, and consequently death, but as the difference of the capacity of the thorax differs one-fifth of an inch only between inspiration and expiration, this difference seems to him too small to suppose that it either prevents or delays the pulmonary circulation to any extent, and therefore he endeavors to explain the asphyxia by the chemical changes which the air undergoes when it comes in contact with the blood in the lungs.

In 1790, Robert Menzies upheld an inaugural dissertation at Edinburgh in which he maintained that the methods employed by Goodwyn for the estimate of the thoracic capacity were faulty. He resorted to numerous experiments undertaken to rectify this estimate by two quite different means.

He found that as a result of his experiments the mean volume of air inspired was 40 to 45 cubic inches, instead of 12, as Goodwyn concluded. Menzies then employed this datum to calculate, according to Crawford, Lavoisier, and de la Place, the quantity of oxygenated gas converted into carbonic acid gas and vapor at each inspiration. The quantity of caloric developed by this conversion, the different capacities possessed by these various gases, that which distinguishes the venous from the arterial blood, the amount of blood passing through the heart and lungs per minute, etc., he worked out, and he came to the conclusion that the temperature of the blood in the left side of the heart should surpass that in the right side to the extent of 0.8763° F. The essayist even appears to believe that it is to this increase of the blood heat after passing through the lungs, rather than to the chemical properties that the respiration imparts to this liquid, that should be attributed the power it possesses to cause the left ventricle to contract.

Desgranges, a most estimable surgeon of Lyons in his day, struck by the diversity of manners of death from drowning, with or without the entrance of water into the respiratory tract, tried to show, in a pamphlet published at his native city in 1790, that there are two kinds of death from submersion: one with entrance of water into the lungs, which he calls "submersion asphyxia with matter, from suffocation or obstruction," while the second, without the existence of water in the respiratory tract, he terms "nervous submersion asphyxia without matter, or from exhaustion." In the latter form, the organs being free, one may hope to obtain a recovery by medical aid, because syncope is a state which may be endured for some time without a lethal outcome.

In a dissertation on the suspension of respiration by submersion, strangulation, and suffocation, which appeared in London in 1791, from the pen of Edward Coleman, the writer just remarks that a misnomer is employed when, speaking of the state of the cardiac cavities, one says that they are more or less filled or more or less empty of blood, since, no matter what may be the quantity, they invariably contract on it, and there is never emptiness. Therefore, they are more or less distended because they do not contain an equal quantity.

Coleman undertook several experiments in order to exactly determine this difference, and to attain his end he drowned several animals, and opened them at once and then placed ligatures on all the large vessels, after which he carefully collected and weighed all the blood which was contained in both ventricles.

The mean result of his experiments gave thirteen parts of blood in the right ventricle and seven in the left. Now, Goodwyn thought that those who died submerged emptied their lungs more completely than in any other kind of death, because the efforts made to breathe only resulted in several successive expirations but no inspiration, while ordinarily life ends in a single expiration.

In order to settle this question experimentally, Coleman drowned several animals, opened them as soon as asphyxia had taken place, and passed a ligature under the trachea. The pharyngeal end of the trachea was then connected with a tube filled with water and placed in an overturned vessel and the ligature removed. The lungs were compressed in order to express all the air contained in them, and it was found that never so much as one-tenth of the volume of air they were capable of containing by insufflation came away. Occasionally, none came away at all.

Coleman repeated this experiment on animals suf-

focated by nitrous air with the same result, and, what was more surprising still, the experiment likewise succeeded in strangulated animals, a fact which showed that the muscles serving expiration contracted with sufficient force to overcome the obstacle that strangulation offered to the exit air, although the atmospheric weight was sufficient to allow the entrance of air into the trachea, although compressed by a cord.

Post mortems of strangulated animals, or those suffocated by nitrous air, offered the same appearances as those met with in drowned subjects, so that it appeared likely that the immediate cause of death was the same in each instance. In order to determine this question, Coleman entered upon theoretical considerations on animal heat, from which it resulted that if the contractions of the right ventricle subsist in asphyxiated subjects for a long time after those of the left ventricle have ceased, far from maintaining, as did Goodwyn and Curry, that the left ventricle is incapable of contracting from the stimulus of the blood before it has undergone the changes imparted to it by the oxygen in the lungs, this is due to the fact that the blood which is in this ventricle, having lost its "latent heat" by circulating in the lungs, is less capable of maintaining the irritability of the muscular fibers, with which it is in contact, than the blood contained in the right ventricle. Therefore, if the blood contained in the right ventricle of drowned subjects could be made to pass into the left, and *vice versa*, it seemed probable that the right ventricle would contract for a shorter time, because the blood contained in it would be less rich in caloric and overcharged with carbonic acid than that in the left ventricle.

From this you will see that Coleman supposed that it was principally by distention of the heart with blood that contraction of the organ was done, and that its *qualities* did not count. He also was of the opinion that the lungs of asphyxiated subjects were in a complete state of collapse which prevented the passage of the blood of the right ventricle to the left.

I shall not refer to the work of James Curry, as it does not advance the question under discussion, but before closing this lecture I would say a few words on a little opuscula published in 1800 by a Geneva surgeon of considerable local repute, although not generally a name found in works on the history of medicine. I refer to Pierre Fine and his work entitled *De la Submersion, on Recherches sur l'Asphyxie des Noyés, etc., Paris,* an 8 (1800).

I shall simply quote one paragraph from this little work to show the enlightened views of its author: "Quelles que soient les différentes opinions des auteurs sur la cause de la mort des noyés, rien n'est plus certain que c'est la privation d'air, la cessation de la respiration qui les fait périr en faisant cesser la circulation du sang. Si l'on veut pousser trop loin cette théorie, pour expliquer de quelle manière l'air est utile à la respiration, et conséquemment à la circulation du sang, comment enfin la respiration de cet air cause la mort, tout devient hypothétique: de la résultant des raisonneurs plus ou moins spécieux, tous susceptibles d'être affaiblis ou détruits par des objections plus ou moins fortes, parce qu'il n'est pas donné à l'homme de découvrir les causes premières; la nature lui en fera vraisemblablement toujours un secret. Ce qu'il y a de bien certain, c'est que la respiration est une condition essentielle pour que la circulation ait lieu; que, pour respirer, il faut de l'air; que lui seul est respirable; que le plus pur est celui qui convient le mieux."

Xavier Bichat's immortal work, *Recherches Physiologiques sur la Vie et la Mort* contained all the requisite explanation for death from drowning. Like John Hunter and Coleman, Bichat believed that the blood remained dark on account of an interruption of the chemical phenomena normally occurring in the lungs. Asphyxia does not occur, as Goodwyn and Curry thought, as a result of "black blood" being devoid of stimulating properties acting on the contractile function of the cardiac muscle, but rather because "dark blood" gives rise to death on account of a sedative action which it exercises over the nerves; while red blood, on the contrary, excites, and by its nature maintains life of all the parts of the organism.

Bichat then modestly adds that he simply offers this idea without attaching too much importance to it. He then goes on to say that no matter how probable an opinion may appear, so soon as careful and exact experimentation is unable to prove it, every judicious mind will attach no importance to it.

Such is, briefly, the history of the cause of death from drowning down to the year 1800, which brings us to the modern school of forensic medicine, with the well-known names of Orfila, Tardieu, Brouardel, Taylor, Christison, Casper, and a host of others.

3 Rue Bellot.

SURGERY AND PSYCHASTHENIA.*

By W. P. MANTON, M.D., F.A.C.S.,

DETROIT.

THE report of the following case might furnish text and exegesis for the subject which I desire to discuss, but further remarks are appended.†

Miss X., a farmer's daughter, aged twenty, was admitted to a State Hospital in December, 1907. A maternal aunt was insane; the father is eccentric, the mother "nervous" and vacillating; a sister had an attack of insanity from which she recovered; another sister is ill-balanced. The patient was in good health until twelve years of age, when menstruation was established. She then became very nervous and had cramps in the abdomen and pain at the end of the spine. These symptoms recurred with each monthly catamenia. Beginning at this time, and continuing to the date of her admission, she was subject to obsessions. She did foolish things that she knew she ought not to do, and worried over trifling matters. These obsessions became more and more marked, until they destroyed her comfort. As an illustration of this, on one occasion she felt that she must not look at her mother, and did not do so for a week, and was then unhappy through remorse. When she yielded to these impulses she at first experienced a sense of relief, but afterwards became miserable from giving way to them, feeling ashamed for her foolish actions. When she resisted them she became wretched and uncomfortable. She was unable to apply herself to any work, was ner-

*Read before the Detroit Society of Neurology and Psychiatry, Dec. 5, 1918.

†For the early history of the case, and hospital notes, I am indebted to Dr. E. A. Christian, Superintendent, and Drs. Morse and Bachelor of the Hospital Staff.

vous and could not properly carry out what she undertook, being obliged to do things over and over again. These obsessions and her dissatisfaction with herself led to several attempts at suicide. She concealed her condition from her relatives until about a month before her admission.

A diagnosis of Hysterical Insanity (psychasthenia) was entered. The physical examination on admission revealed a retroverted uterus pressing against the rectum. On account of the stiffness of the abdominal wall, the condition of the ovaries could not be determined but there was tenderness on both sides. From the history of repeated attacks at the menstrual epoch, and the local findings, it was decided that the pelvic pathology might have a decided relation to the mental manifestation, and surgical operation was undertaken in January, 1908. The uterine canal was thoroughly divulsed, the walls curetted, and the internal os incised. The left ovary was found destroyed by a cyst as large as a lemon and was removed; the appendix was bound down by adhesions and was also removed, and the round ligaments shortened by Gilliam's method to bring the uterus up into normal position. The patient made an uninterrupted and excellent recovery from operations. Menstruation set in on February 5, and it was noted that she "had not had any pain for the first time in her menstrual history." She was removed from the hospital in March, 1908, at which time she seemed quite comfortable. The day she returned home she was tired and could not eat or sleep. The following day she displayed something like pressure of activity—cleaned house and applied for a position. On the second morning she was agitated, the impulses reappeared, and she was brought back to the Institution. After her return she was hypochondriacal, suffered from impulses, and attempted to strangle herself. The morning following this episode she was depressed and disinclined to talk, but ate heartily. She had morbid impulses and thought there was no hope for her. Becoming more comfortable, she was allowed the freedom of the grounds, but her symptoms returned and she became confused and unable to decide upon things, and talked about not being willing to live any longer. She made several attempts at suicide by choking herself with a towel, but these digressions did not bear the aspect of sincerity. In August she was removed from the Hospital by her friends.

The following November she wrote from a Western city to one of the hospital physicians, that she was well and wondered why she could have wished to die. "I came out here," she writes, "on a six months' visit. I feel quite lonely, as I know only two people, my sister and brother-in-law. I am as free as a bird and happy as a lark; no more suffering either mentally or physically, and I owe it all to your skill and kindness. Shall never cease to be grateful to you for all that you have done for me." During the early summer of the next year (1909) in another long letter to ——, she describes her experiences as a pupil nurse in a hospital. It is understood that she subsequently gave up the course when she learned that a patient to whom she had engaged herself was already a married man. Following this she traveled in the West, and was not again heard from until Sept. 5, 1911, when she appeared in my office complaining of dysmenorrhea. She was very talkative and appeared to make much of trifling bodily discomfort. At the beginning of the interview she suddenly burst into tears caused, she said, by the fact that her mother had told her she might have to lose the remaining ovary, and she "wanted children." Her self control, however, was markedly better than formerly. The menstruation was regular, every twenty-one days, lasted two or three days, but was slow in starting, during which time she had "awful bearing down pains" and an "awful disagreeable feeling at the end of the spine." When the flow was fully established there was no further discomfort. While in the West she had had an operation on her nose, but it was not ascertained whether this was for the relief of the dysmenorrhea or not. She had no headache or backache, the appetite and digestion were good, and she slept well; she said that she was not "nervous," and, save for the temporary monthly annoyance, "felt fine." Examination showed the uterus to be in normal position, small and freely movable, but with sensitiveness at the internal os. A diagnosis of chronic endocervicitis was made.

The patient being desirous that something should be done for the relief of the painful menstruation, dilatation, curettage, incision of the internal os with the insertion of an intrauterine stem pessary were carried out at the Woman's Hospital. The stem was worn for three months, and the patient dismissed in satisfactory condition. Two years later she was married secretly, and nothing further was heard from her until, in reply to a letter of inquiry regarding her condition, under date of November, 1918, she writes: "I am feeling fine. I can do all kinds of hard work, such as lifting, etc. I do my own housework, and the only time I feel nervous is just before the period. I am naturally of an excitable nature. Menstruation is very regular and continues three or four days. The first day of the period I have quite a lot of bearing down pains, until the uterus is fully dilated; after that (generally the second day) I begin to feel fine. Fearing the results, have never allowed myself to become pregnant. I have never had any miscarriages. Have no family of my own, but have taken an infant to raise—a war orphan. Physically I eat and sleep well, also I am full of ambition. I feel very grateful to science, and had it not been for your skill I would no doubt to-day be at the asylum, hopelessly insane. The operation surely was a success."

The case recorded presents a typical picture of psychasthenia — obsessions, imperative impulses, "clear consciousness, the patient fully recognizing their abnormal nature" (White), remorse for foolish actions, endeavors to overcome them, and a will power weak, inefficient, and unable to control. Back of all a neurasthenic heredity, and prominent in the foreground a pelvic pathology capable of producing great somatic distress and suffering. Certainly here was an instance where, by the removal of the pelvic complications, surgery might be expected to effect immediate and marked results. The history of the patient subsequent to operation, however, does not appear to have fulfilled these hopes, and it will be observed that not until she was removed from the family environment (a separation which has practically continued up to the present), and was placed in new surroundings, amid new scenes, and engaged in new and unwonted occupation, were the mental manifestations apparently cleared. There can be no doubt that the surgical treatment did very much in promoting this end, and it is questionable if this could otherwise have been attained; but would it be a correct and logical deduction to assume that the surgery was the most important factor in determining the recovery?

Psychasthenia is curable in most cases if taken early—before mental deterioration has set in—and is usually best treated by asylum methods; surgery, although most important where indicated, should be considered only as an adjuvant in forwarding the convalesence. And this brings me to the intent of this paper: to protest against the unwarranted claims which are often advanced, and to reassert that after more than thirty years' experience, in spite of the declarations of certain surgeons and others to the contrary, I still maintain what I stated at the beginning of my investigations, that insanity is not curable by surgical means alone.

As the first in this country to take up surgery systematically among the insane, large opportunities have been offered for observation, and I have yet to see the instance where surgery has played more than a secondary, although often a most im-

portant, part. It is possible that difference of opinion may lie more in statement than in fact. I am a surgeon and not an alienist, and my bias, if such existed, would naturally be toward the achievements of surgery; but in the claims of others for curative chirurgical successes among the insane I see only a narrowed conception of the subject, and an inadequate credit accorded asylum treatment, which, from my point of view, should be considered first and paramount.

To the lay mind and, unfortunately, to the minds of many in the profession, the spectacular appeals most forcibly, and the ultimate recovery of the mentally afflicted patient who has been subjected to operation is credited to the latter rather than to the preceding and subsequent institutional care. I have always maintained that somatic irritation may be an important source of aggravation to the mental disorder, and that, in whatever part of the body it may exist, it should, as far as possible, be removed, either by surgical or other means—even in the most hopeless cases of mental degeneration. It is quite evident, however, that insistance that surgery is a panacea for insanity has done much harm among those who grasp at every straw which may appear to offer relief.

What is one to conclude from the following announcement which has been sent broadcast through the daily press? "Are we," says an editorial in *American Medicine*, "on the threshold of a new and revolutionary conception of the causation of insanity?" I quote from the newspaper clipping: "Cure of insanity by extracting diseased teeth, removing affected tonsils and clearing the gastrointestinal tract was announced here to-day by Dr. ———, Medical Director of the ——— State Hospital, in a report to the State Department of Charities and corrections. The report gives results of eleven years of experimentation on a number of deranged patients, and states recoveries are not only speedy under the new treatment, but that sanity has been restored in some who had been in the hospital nine years. Causes of infected teeth were charged by Dr. ——— to bad dentistry and promiscuous kissing." If our trust is to be put in the "legs of such horses," it will not be long before our institutions for the insane will be overrun with patients, toothless, tonsilless, and over-kissed (God save the mark), who have been promised mental cure, just as happened a few years ago when the removal of healthy ovaries was heralded as the unfailing remedy for all mental aberrations in women. Whether we regard them as true or not, such claims are mischievous because they are misleading.

Surely the causes of insanity are not limited to septic infections, toxemias, or to any other single factor.

The great importance of focal infections in relation to a large number of systemic and local diseases, so ably illuminated by Billings in his Lane Lectures of 1915, is now too well recognized to demand comment, and there is no reason to deny that the same relationship may and probably does exist to a greater or lesser degree between infections and certain derangements of the mind. This has been found to be so in the incidence of syphilis, in which Peterson suggests that the action on the brain may possibly be the result of toxines arising from the specific (syphilitic) microorganisms. In a recent communication, Duke has shown (Multiple Infections, etc., *Jr. Am. Med. Assoc.*, Nov. 23, 1918), that the coexistence of syphilis of the nervous system and chronic sepsis is common and very important, since the former may be rendered worse by the presence of the latter. The same is also true of tuberculosis and other conditions.

But—just as the early development of delirium in the course of typhoid fever is something of an index of the nervous and mental stability of the individual, so the broken mind in cases of septic infection may be taken as a mark of weakness in mental integrity. Thousands of people with carious teeth, pyorrhea, abscessed tonsils, pus tubes, and the like never show evidence of what White terms "lowering of the psychological tension," although they do frequently exhibit symptoms, general and local, secondary to the local or systemic poisoning. It is therefore reasonable to conclude that, in the few instances which may be thus affected mentally, there is an underlying stigma back of the acute or chronic processes. As long ago as 1892 I entered a plea for the amelioration of insane women suffering from local disorders. This was intended to cover both sexes afflicted with removable bodily conditions which could in any way prove a source of irritation to the mental disease; for the insane are as much entitled to relief from suffering as are the sane. I have never, however, urged that such relief would lead to mental cure.

The advertising of cures, such as mentioned, failing to distinguish between the forms of the psychoses, puts the matter in a false light before both the profession and the laity and engenders hopes which are doomed to disappointment.

Most observers will, in the main, agree with a recent writer (G. W. Brown, Tr. Medico-Psychological Assoc., 1917, p. 449), who declares: "It can be stated without fear of contradiction that a large number of patients who reach mental hospitals would not develop psychoses if their somatic diseases were diagnosed in their incipiency and the proper treatment administered."

What is desirable is not imaginary flashlight images of mental cures, but a more careful and critical investigation of cases and a saner analysis and interpretation of the part played by every remedy employed for the relief of the mentally sick.

SPANISH INFLUENZA.

BENEFICIAL RESULTS OF CONTINUOUS STIMULATION OF THE HEPATIC DETOXIFYING FUNCTION BY MILD DOSES OF CALOMEL.*

By W. L. MANN, PH.B., A.M., M.D.,
Lt. Comdr. U. S. Navy.
Marine Barracks, Quantico, Va.

The pendulum of professional, as well as public, opinion presents a tendency to vary from one ex-

*This article is written under the assumption that calomel acts as an hepatic stimulant. Its mode of action and the correctness of this assumption are beyond the scope of this paper. Notwithstanding the results of experimentation, it appears to be the consensus of opinion among practising physicians, especially those with tropical or sub-tropical experience, that calomel exerts a certain hepatic influence.

treme to the other. This is especially true of therapy in certain diseases.

During the recent epidemic of influenza, with its sequela, pneumonia, the medical department of this Post had an opportunity to use as a routine measure one of the well-known remedies with gratifying results.

It has been the experience of the writer that recent graduates in medicine have been reluctant about the use of calomel, and have relied principally on oils and saline laxatives. The older school of medicine has probably gone to the other extreme, and has given such large doses of this medicine, on occasions when it was not required, that it is possible that this is explanatory of the fact that the pendulum of professional opinion has now appeared to have swung to the present extreme of conservatism.

During the above mentioned epidemic some rather striking results were obtained from calomel therapy on a few cases that were indirectly under my supervision. This was at first regarded as, perhaps, a coincidence.

After observing over three thousand cases of the so-called "Spanish Influenza," it appears to me that the disease is essentially a toxemia. Some of the cases considered as pneumonia appear to be more of a pulmonary congestion and edema, with expectoration of blood-tinged mucus; although there were many cases of purulent expectoration where typical symptoms of lobar or lobular pneumonia were noticed.

Detoxication is one of the many functions of the hepatic gland. For example, it appears that a larger amount of certain toxins may be injected into the portal vein than into the hepatic vein without fatal results. This is assumed to be due to the detoxifying action of the liver.

Acting on the assumption that the toxemia might be combated to some extent by stimulation of the hepatic function by mild doses of calomel, the following procedure was eventually adopted as a routine: (1) Calomel gr. ¼ given every half hour for six or eight doses, followed by a mild dose of magnesium sulphate in the morning, or preferably, if patient was very ill, an enema was substituted. (2) Calomel gr. 1/10 was then given four times a day for three or four days.

The above routine was made flexible and elastic so as to permit individualization of treatment. In many cases where the fever tended to show secondary rises, or to remain high, the administration of two grains of calomel in fractional doses was repeated with rather good results.

In some cases nausea may be caused by these fractional doses of calomel and, if so, it should be discontinued temporarily, although in many cases nausea and vomiting was one of the pronounced symptoms of the disease.

The routine use of calomel was not adopted until the fourteenth day of the epidemic, therefore the presentation of any statistics on the mortality rate before and after its adoption might lead to fallacious deductions, as there are other factors which enter into consideration.

It will suffice to state that the wards which first adopted this treatment presented a much better appearance and a lower mortality rate than the other wards. Also, since the adoption of this therapy as a routine, the ward medical officers are unanimous in their opinion that beneficial action has resulted from its use; however, their individual opinions, as to be expected, show varying degrees of enthusiasm about its success.

Notwithstanding the apparent beneficial action of this treatment, the total number of fatalities from this disease on this station is rather disappointing; however, the indications are that the case fatality rate will probably compare favorably with other places.

The best results were obtained in the early treatment of cases by this method. The cases of influenza that had progressed for some days failed to respond to calomel as readily as the incipient cases.

Of course, it is assumed that other remedies will be used in conjunction with this therapy.

Summary and Conclusions.—1. The influenza cases treated with an initial calomel purge followed by 1/10 gr. calomel, four times a day, presented less toxic symptoms, nausea was not so pronounced in many of the cases, and the mortality rate was not so high.

2. The beneficial results were rather striking, although no specific action is claimed.

Medicolegal Notes.

Testimony of Medical Witness Attending Plaintiff.—In an action for personal injuries to an employee it is held that the admission of testimony of a medical witness who treated the plaintiff nearly a year after the injury was not erroneous in giving a history of the case as given to the witness by the plaintiff, where the witness apparently testified from his own knowledge and examination. His statement that the plaintiff did in fact give him a history of the case was immaterial.—Plunkett-Jarrell Grocer Co. v. Johnson, Arkansas Supreme Court, 206 S. W. 677.

Action for Services, Etc.—The Supreme Court of California holds that a complaint, in an action for services and for medicine furnished, including an alleged indebtedness to two other physicians, who had performed services for the plaintiff with the defendants' consent, stated a single cause of action in favor of the plaintiff alone, and judgment for the plaintiff (174 Pac. 903) was affirmed.—Myers v. Canepa, (Cal.) 174 Pac. 906. The services of the two other physicians, as alleged in the plaintiff's complaint, consisted of consultation and advice, and assistance in the performance of surgical operations, their charges being made against the plaintiff personally, and not against the defendants. —Myers v. Canepa, (Cal.) 174 Pac. 903.

Insufficient Evidence of Negligence.—In an action for damages for personal injuries by negligence it appeared that the plaintiff, then between two and three years of age, suffered from hernia; that the defendant was consulted by the plaintiff's father; that hernia is not easily located in a child of that age, and there was some doubt as to which side it was on. It further appeared that the father decided that it was on the left side and directed an operation, which was successfully performed, a hernia being found. Two weeks later the defendant was called again to see the child, who, he was informed, manifested pain, but failed to discover anything. He told the parents to inform him if there was any evidence of hernia on the right side, as he thought that might be the trouble. Three weeks later the father called on the defendant and demanded a return of the money paid for the operation on the ground that it had been performed on the wrong side, and informed the defendant that a lump had appeared on the right side. The defendant offered to operate again without charge, but the father would not agree. It was held that this evidence was insufficient to support a verdict for the plaintiff.—Verbitzley v. Cunningham, 207 Ill. App., 128.

Military Medicine.

Wooden Limbs in the Making.—An industry which has unfortunately received an enormous impetus through the war is the manufacture of artificial arms and legs, and an interesting description of some features of the work was given recently in the *British Engineer*. In Great Britain, at any rate, the majority of artificial limbs are constructed of wood, and willow, of which cricket bats are made, has proved the most suitable for the purpose. One difficulty brought about by the greatly increased demand was the seasoning of the timber, which in the ordinary course of events would have taken two years. Messrs. Yarrow of Glasgow, the noted builders of naval craft, who have interested themselves in the matter, found that, if the trees were cut into two foot lengths and a hole was bored through the center of each, the lengths could be dried in a few weeks by circulating air round and through them. Some idea of the dampness of the wood when the trees are felled may be gathered from the fact that a sample piece was reduced in drying from 13 lbs. 6 ozs. to 5 lbs. 8 ozs. Various sizes of limbs are standardized leaving only the actual fitting to the stump to be done at the hospital. The metal parts, such as bolts for knee and ankle joints, and the steel springs for flexing the ankle, are standardized for all sizes. It is interesting to note that in Scotland, following Messrs. Yarrow's lead, no fewer than eleven engineering and ship building firms are making artificial limbs. Moreover, the work is being done at cost price, the only desire of the concerns engaged in it, being to help those who have lost limbs in the defense of their country.

Intravenous Injections of Hexamethylenamine.—The action of this drug on infections other than of the urogenital tract is a matter concerning which much difference of opinion has existed. There appears to be no doubt that when it is given in febrile conditions the usual febrile urine may not be in evidence. Many practitioners use it under one name or another as a routine measure in infections of all kinds, much as quinine was and still is used. Last summer two French physicians reported favorable results from the intravenous injections of the drug in medical infections. No untoward results were seen, and this is also true of intramuscular infections. In the *Progrès Médical* for November 16, Achard reports cases of injection of the drug in surgical infections. There were 7 cases of septicemia in which there had been for several days high temperatures. The patients were soldiers with gunshot wounds of bones or soft parts. The total daily dose was 1.25 grams. There was no immediate reaction, but on the following day a marked diuresis occurred. Patients who had been passing 500 c.c. of urine passed two and even three times that amount on subsequent days. The diuresis was progressive under the treatment, and eventually reached 2 liters. There was no corresponding fall of temperature, so that the phenomena of effervescence were incomplete. There were no complications or sequelæ on the part of the liver, kidneys, or other organs, after exhibition of the drug. This immunity may prove to be general, in which case the remedy should be hailed as a prophylactic against the complications and metastases of septicemia.

Harvard Unit Arrives.—The Harvard Unit, made up of 27 medical officers and 103 nurses, which was organized in 1915 and has since been in continuous service in France, arrived in Portland, Me., on the White Star steamship *Megantic* on January 30. Altogether the doctors and nurses of the Harvard unit cared for 126,000 wounded at General Hospital No. 22 and approximately 27,000 at clearing stations and on hospital trains. General Hospital No. 22 which was the base of the Harvard unit was raided from the air on many occasions. At one time thirty-eight medical officers were saved from certain death only because they were called out in the night to receive a large convoy of British wounded. During their absence their quarters were entirely demolished by a bomb from an airplane. Lieut. Col. Hugh Cabot was in command of the unit. Only one per cent. of the wounded cared for by the unit died.

Congress Will Probe Hospital Charges.—Statements by soldiers alleging brutal and inhumane treatment at various hospitals of the country have recently been given considerable newspaper publicity and are to be the subject of investigation by Congress. A committee of seven members of the House with powers of Court to compel attendance of witnesses and the production of papers has been proposed as the only means of getting at the truth or falsity of the charges. A resolution providing for such an investigation was introduced into the House and referred to the Rules Committee.

Red Cross Sends Relief to Poland.—The American Red Cross Council, of which Henry P. Davison is chairman, has decided to send a relief commission into Poland. Aside from the imperative need for food and clothing the opportunity for medical services, nursing, etc., is practically unlimited. The commission will carry drugs and medical supplies at once. Dr. Walter C. Bailey of Boston is head of the commission and Major F. E. Fronczak, Health Commissioner of Buffalo, has been detailed by the United States Army to the Red Cross specially for this mission. Several other physicians and twelve Polish-American nurses will accompany the expedition.

Serbia Needs Mobile Hospital.—Madame Grouitch, wife of the Serbian Minister, and herself a commissioner of the Serbian Government to this country, at a recent meeting of the American Women's Hospitals, made an appeal for medical assistance for the population of Serbia. She declares that there is a most pressing need of two mobile dispensaries, with ambulances, each possessing fifty beds, to go from town to town. Each mobile dispensary will require two doctors, one dentist, and six nurses. Madame Grouitch states that Serbia has only 140 doctors of her own left, the rest having been killed in war or having died of disease. The American Women's Hospitals, co-operating with the American Red Cross, will send a medical personnel to Serbia as soon as passports can be obtained. Those who

are going include the following: Dr. Minnie C. O'Brien of San Antonio, Texas; Dr. Katherine M. Cook, Pittsburgh, Pa.; Dr. Mary H. Elliott, Columbus, Ohio; Dr. E. F. H. Greene, Fergus Falls, Minn.; Dr. Lulu Hunt Peters, Los Angeles, Cal.; Dr. Helen F. Ratterman, Cincinnati, Ohio; Dr. Harriet Gervais, Dorchester, Mass.; Dr. Sarah Elizabeth Foulks, Burlington, N. J.; Dr. Edna Ward, Denver, Col.; Dr. Marie Hyndeman, New York City. The American Women's Hospitals has recently received a gift of an ambulance from the Patriotic Penny and the National Special Aid Society of Wilmington, N. C., and in addition donations of over $2,500. At this meeting a telegram was read from Dr. Caroline M. Purnell of Philadelphia, commissioner for the American Women's Hospitals in France, stating that Major Gibson, manager of the Red Cross in France, has allowed $50,000 for the maintenance of the society's hospital at Luzancy.

Influenza Takes Off Many Nurses.—The Red Cross Headquarters at Washington has made public figures covering the losses in the nurses' personnel here and abroad that have been caused by the epidemic of influenza. These figures show that more than 200 American Red Cross nurses have died of influenza contracted while ministering to soldiers stricken with the disease. It is also reported that there are returning to America many New York Red Cross nurses who have contracted tuberculosis at the front and whose condition demands immediate treatment.

Instructors Wanted for Disabled Men.—The Surgeon General's office announces that 10,000 disabled soldiers and sailors are now receiving educational training in forty-three of the army hospitals. A call has been sent out for additional instructors and supervisors. Officers and enlisted men desiring transfers to this service have been instructed to apply to the Division of Reconstruction in Washington. The House has passed and sent to the Senate the bill appropriating $10,000,000 for constructing hospitals for disabled soldiers and sailors.

Wounded Sixty-eight Times.—Sergt. John W. Grimmer, formerly a chauffeur of the Consolidated Gas Company of New York, who after all the commissioned officers had been lost took the remnant of his company through the Hindenburg line, is truly a battle scarred veteran. He was gassed and emerged from the fight with sixty-eight pieces of shell in his body, which have since been removed. Among his injuries were three machine gun bullet-wounds in right thigh. After receiving these wounds he lay all day under shell fire and was then carried four miles to a dressing station, but as they were too busy to care for him he was taken twenty miles further in an automobile to a tent hospital.

Rules for the Release of Sick and Wounded Soldiers.—Surgeon General Ireland has announced the policy of the War Department in reference to sick and wounded soldiers at military hospitals. They will be retained only long enough to restore their health to a degree which would permit them to return to their former occupations. The effort will be made to avoid exposing them to hospitalization. Men to be retained under military control are those suffering from acute diseases or unhealed lesions, from communicable diseases, from disabilities that can be corrected within the term of enlistment of the patient, and those suffering from chronic or permanent disabilities which are susceptible of improvement and who may be fitted for the industrial opportunities of the training course provided by the Federal Board for Vocational Training. Soldiers who have been blinded or their eyesight much impaired will be retained until they are able to care for themselves or are otherwise physically fit for discharge. Cases of amputation of the leg or arm are to be kept in the hospitals until provisional artificial limbs or arms are provided and reasonable proficiency in their use is reached.

Major Richard Derby, who has been serving with an American medical unit in France, has returned to this country and will resume his practice in New York. Major Derby has received the French war medal for bravery in visiting aid posts without regard to the artillery and machine gun fire. He was at one time knocked down by a shell.

Dr. Dudley Roberts has been released from military service and will resume his practice at 84 Remsen Street, Brooklyn.

Dr. Julius Dworetzky, formerly of the Otisville and Sea View Hospitals, who has been in service in France, has returned and will resume his practice of medicine in the specialty of tuberculosis, at 7 Law Street, Liberty, N. Y.

Deaths in the Service.—Lieut. Samuel Victor Rosenkranz, M. C., U. S. Army, of Los Angeles, a graduate of the College of Physicians and Surgeons, Los Angeles, in 1915, aged 28 years, died in the United States Marine Hospital in San Francisco, on October 20, from pneumonia following influenza.

Asst. Surg. Lieut. Thomas Joseph Courtney, U. S. Navy, of Worcester, Mass., a graduate of Tufts College Medical School, Boston, in 1912, on duty at Norfolk, Va., died on December 27, aged 32 years.

Lieut. Gerhard Frederick Hartwig, M. C., U. S. Army, of Young America, Minn., a graduate of the University of Illinois, in 1915, aged 29 years, who was on duty in France, was killed in action on October 31.

Lieut. Royden Benedict Roder, M. C., U. S. Army, of Northwood, Iowa, a graduate of Hahnemann Medical College, Chicago, in 1909, died at Camp Custer, Battle Creek, Mich., on December 9, from pneumonia following influenza, aged 33 years.

Lieut. Joseph Louis Schwarts, M. C., U. S. Army, of St. Louis, a graduate of the St. Louis University, in 1911, on duty at Fort Oglethorpe, Ga., died of pneumonia on December 24, aged 33 years.

Lieut. Guthrie Olaf Burrell, M. C., U. S. Army, of Bucyrus, Ohio, a graduate of the Ohio State University, Columbus, in 1916, aged 26, was killed in action in France on September 28.

Lieut. Lloyd Reuben Boutwell, M. C., U. S. Army, of Kansas City, Mo., a graduate of Washington University, St. Louis, in 1916, aged 29 years, is reported to have died of wounds received in action, in France, on November 14.

VAGABONDAGE AFTER THE WAR.

ALTHOUGH the Great War now apparently coming to a close will become less and less popular with the magazine authors (whose favorite representation of the war's influence on individual psychology is a young man who has always been timid, not to say cowardly, and who is suddenly inspired by some incident—the variation of this incident forming the material for more stories and more checks—and goes forth to fight and returns medal-decorated), serious students of both individual and collective psychology will find much material afforded them by demobilization and the return of soldiers for a day to the work of a lifetime. Having gotten safely through that sentence, we can be more specific. The complete alteration of an individual's whole habit of life can indeed be accomplished and has been in millions of instances in the past few years, but his life cannot so readily resume its old status. The urge of patriotism and the threat of national disaster have caused men in all the Allied countries to forsake the desk for the army tent—a sedentary life has been exchanged for the most active kind of outdoor one. For the past year or two or three these men have been tramping about in the open, eating plain food, and sleeping on hard beds, acquiring thus a superabundance of health and vitality, feeling as they have never felt since they were children.

The lure of the open has been sung by many poets, but to the average civilized man it is a pleasant myth to be considered as stories of Alaskan adventures are considered when one sits in the deep leather chair with the electrolier shedding its soft radiance over one's book and the open fire lending a touch of color to the steam-heated apartment. Now and then, to be sure, the city man camps out for a week or so to the accompaniment of aching muscles, mosquitos, poor coffee, and general ennui. Later on he looks back on the adventure as rare sport and recalls with his friends the night they sat and played penny ante with their umbrellas up because the roof of the tent leaked, and he talks of going camping again, but down in his heart of hearts he knows how well he likes the comfort of city life, or any life lived within four walls, and thinks the poet's song of the delight of the open is a sort of pleasant fiction, very much as when he tells the ocean to "Roll On!"

But the great war has put a new aspect on the thing. These same men have been taken out into the open and made to live there. They have not been allowed to quit. And from loathing it they have come to dislike it, then to endure it, then to like it, and finally they are fascinated by it. And now comes demobilization. These men can return and take up their sedentary occupations again. But will they?

It is a fact well known to students of sociology that following every great war of the past there has been an increase of vagabondage in the warring nations, nor is this one expected to be an exception. Psychology as it affects the individual and his life is very little known, after all. How many persons are thrown by destiny into foreordained paths and go from toys to school, from school to desk, and from desk to the grave with no possibility of kicking against the pricks unless it were by the exercise of a greater force of will than in them lies. They take the line of least resistance and follow the career mapped out for them. If they ever contemplate the delicious freedom from responsibility, it is only with a passing sigh and no actual appreciation of its delights. The iron bonds of custom, convention, and conscience are too strong for them and they go down to the grave highly respected citizens. But the war has given them physical health, self-reliance, and a taste of freedom. The Wanderlust grips them, the open road of Bliss Carman, the long trail of Kipling, the little voices sung by Service are calling them and they go forth into the open spaces. So we shall doubtless see as one of the many by-products of the war a rebellion against convention and civilization and an increase of society's Ishmaels.

THE COVENTRY SITUATION AND THE BRITISH MEDICAL ASSOCIATION.

So long as representative bodies, of whatever dignity and authority, are composed after all of ordinary men it must be expected that motives will be complex and actions not always well directed. Neither august name nor tradition apparently is sufficient to prevent the exercise of certain emotions and the carrying out of certain points of view which may rightly be questioned. It is necessary, occasionally, to submit to a broader test and a keener touchstone of progress and experience, some of the conventions of such bodies as the British Medical Association and its counterpart in our own country. Under the rationalizing guise of protection for their members and certain professional standards, they too often prohibit a more progressive individualism from establishing and carrying

on some new but most practical form of service. The standards need a frequent readjustment to changing conditions and the realism of social needs lest they prove utterly artificial, a hindrance rather than a safeguard to the actual ideals of these associations and a cover for petty individual feelings which are masking under such sanction.

Certainly there is occasion for serious thought and self-examination on the part of our American Medical Association in the judgment recently pronounced in the case of Pratt and others against the British Medical Association. This small group of doctors in Coventry sued the Association and three of its local members for "conspiracy, libel, and slander" exercised in restraint of the defendants' service upon the medical staff of the Coventry Dispensary, and extending to their professional and social discrediting. The matter had been pending for many years until through the judgment recently given the defendants were awarded over $18,000 damages and heavy costs, although the case will still be appealed.

The *British Medical Journal* published a very full report of the proceedings, including the principal features of the case, its history, and the protracted hearing, in its issues of August 3, 10, 17, 1918, and besides other notes upon the case devoted a supplement of seven or eight pages in the issue of October 26 to a full report of the judgment. It is the matter of this report which stimulates reflection and question as to the motives upon which individuals and organizations may act and with which they too often blind themselves. The British Medical Association and its individual members had all along taken the position that they must guard against dishonor to the profession and professional and financial loss to its members through such contract service as that in which the members of the Coventry Dispensary engaged. The defendants, while at the start conceding one important point in regard to securing members for this dispensary, maintained for the rest that no such evils resulted from their service.

Nevertheless, the British Medical Association in its procedures has secured for itself such a charge as the Justice felt, regretfully, bound to make. He considered the disciplinary manner of the association an improper assumption of power, that they had boycotted, punished, and pecuniarily damaged the defendants without just cause in law, that in fact their attempted coercion had been carried out not by legal means but by influence. More than this, they were governed in their method of action by personal spite and ill will. They seem to have manifested in the persistence and extent of their efforts "to make the ostracism as complete as possible," a curious though not unusual feature of power psychology, which is accountable for much zealous misapplication and much personal injustice to individuals or to organizations.

This is the thing which demands more rigid examination, with a courage which welcomes the exposure of possible self-blinded motives. For this will lead to greater fairness and tolerance with newer forms of service, such as constantly changing social conditions bring, and so prove truly protective and useful. Progress is, however, hindered and blocked under the cover of a too rigid protection and guardianship of that which already exists. It is a self-absorbed paternalism, of just that sort that claims that the father's word is law, merely because it has been long established and the unconscious power sense of the parent can see no room for other concepts, other responsibilities of action than his own. Such power runs strangely to cover and unintentionally disguises itself under the protection and other seeming advantages which it creates. And as in the Coventry case it gives opportunity too often for ends and methods of perhaps unconscious personal spite and envy.

So our own American Medical Association has set its face against a number of innovations from the mercantile world and from certain alert minds in the profession who can seize a truly greater avenue of usefulness by some extension of means and methods, and against some of the means of progress which could save the profession from the stagnation of too great conservatism. It, too, has fallen into the danger of so pulling the hood of its authority and of its high ideals over its vision that it fails in many instances to separate the true and useful from the false exploitation of drug, method, organization, whatever it may be that marks an actual progress and practical service in the field of medicine. Neither in Great Britain nor in our own country can the Medical Association lend itself to the exercise of restraints or of personal or organized influence in a manner which could never be legally tolerated in the world of commercial business integrity.

CASTOR OIL AND THE WAR.

At first thought, the mention of castor oil in connection with the war will bring to mind its therapeutic usefulness only. However, it may at once be said that it is not as a drug this oil has played a part in the downfall of the Central Powers, but as a lubricant of machinery. Before dealing with its superlative merits as a lubricating agent for the engines of aeroplanes it may not be out of place to discuss briefly the history of perhaps the best and the longest established aperient. Castor oil is easily one of the oldest drugs known. The castor-oil plant appears to be the gourd referred to in the book of Jonah. Hippocrates employed the root in medicine. It is also the κίκι or κροτών of Dioscorides, who observes that the seeds are powerfully cathartic. While κροτών was the name given by the Greeks, the analogous term ricinus was applied by the Romans, on account of a fancied resemblance of its seeds to the little insects known as ticks which bore this name. Its oil has been employed in medicine from the earliest times by Hindus, Egyptians, Greeks, and Arabs. Its use is men-

tioned by Aetius, Paulus Egineta, and Pliny. Different opinions are held as to the number of species belonging to the genus, although there is little doubt that several varieties have been raised to the rank of species. These are found in Java and throughout India, and in fact can be grown in any tropical or semitropical country. Two varieties of the seed are known, one large, the other small. The latter is thought to yield more oil and of a superior quality. The oil consists mainly of ricinoleic acid, together with other fixed oils, a resin, and possibly an alkaloid. The seed contains a drastic constituent, ricin, highly irritant, and therefore more powerfully purgative than the oil. The purer the oil the less active its purgative property.

As said before, its excellent aperient properties, although they may have been used with beneficial effect among the soldiers, have not contributed to any appreciable extent to the debacle which has overtaken our Teuton enemies. On the other hand, the remarkable properties of castor oil as a lubricant have effected much in this direction, in the judgment of those who are qualified to speak with authority. It seems to have proved itself to be the ideal lubricant for the machinery of an aeroplane, in fact, the *Motor Age* says, it is an absolute essential for rotary engines. The fact must be borne in mind that the propellers of flying machines revolve at a rate greater by far than the driving apparatus of any other machine. Consequently, there is developed within the cylinder of an aeroplane engine an intense heat, produced by gas of an extremely high temperature, which will attack and consume most mineral oils. If, by reason of the high temperature of combustion the lubricating oil is consumed, or so thinned out that it no longer fulfills its purpose of preventing or reducing friction between metal surfaces, the result is that the pistons become overheated, expand, jam, and the machine is "stalled." It is in this way that many if not most disasters to aviators occur.

Now, castor oil is not subject to these defects. It is not burned up or thinned out by any heat that the engine of an aeroplane may develop. It is more or less impervious to the effects of temperature, and will maintain its consistency and flow freely through the distributing system, be the temperature of the enveloping atmosphere what it may. Cold appears to have little effect on its lubricating properties, and indeed wide differences in temperature fail to make any marked impression upon it. Because, then, castor oil is the best-known lubricant for the engines of aeroplanes, and because a very considerable supply of the oil has been and is available for the allied airmen, and because the Germans were unable to procure it in sufficient quantities, it is no hyperbole to assert that castor oil has played no mean part in victory. Castor oil has showed itself as effective in lubricating machinery made by the hand of man as for generations it has proved itself one of the best means of regulating the digestive machinery of man himself.

MEDICAL USES OF PARAFFIN.

Before the outbreak of war paraffin had achieved a reputation from both the therapeutic and the esthetic standpoints. Paraffin solidifying at about the body temperature has been employed by subcutaneous injection to correct various facial deformities, and as a mechanical means of relieving chronic constipation, employed by mouth in the form of purified petroleum oil, it has given great satisfaction. In the opinion, in fact, of many authorities it affords a comparatively easy and assuredly harmless method of overcoming intestinal stasic and of preventing the occurrence of many and various diseases. Even if the views expressed as to the therapeutic efficacy of petroleum oil appear somewhat exaggerated, there is little doubt that this mineral oil provides a simple mode of relieving that common condition known as intestinal stasis and is an effective lubricant of the lining of the gastro-intestinal tract. Petroleum oil has also shown its usefulness employed as a spray in certain conditions of the nose and throat.

It may be further said that during the recent epidemic of influenza, liquid paraffin has been used in the treatment of the infection with good results. Dr. C. Muthu, writing in the *Lancet*, Dec. 7, states that he employed liquid paraffin as recommended by White Robertson in four cases of influenza. The bowels were kept freely open by aperients and liquid paraffin was applied to the chest, front and back. All recovered.

During the war, paraffin has demonstrated its value in surgery. Some few years before the war a French surgeon introduced a paraffin mixture with which to treat burns and to which he gave the name of ambrine. However, until the war occurred this method of treating burns gained but a slight foothold. With the advent of war and with the consequent frequent occurrence of burns this paraffin mixture was afforded unique opportunities for proving its worth. Its value has been referred to in the medical journals, and paraffin mixtures have been employed with conspicuous success not only in the treatment of burns but in the treatment of wounds with extensive loss of tissue. The efficacy of the treatment in such cases is said to be due almost entirely to the paraffin content of the mixture. With regard to another kind of wound treatment and one which has met with considerable success, in the healing of war wounds, paraffin has played a very considerable part. It is one of the ingredients of "bipp," which is one of the antiseptics that has been found efficacious in the treatment of war wounds.

INFLUENZA IN THE FAR EAST.

So far as can be gathered from the perusal of the literature of influenza, the pandemic of 1918 was the most widespread of any previously recorded. The disease has been especially rife in Asia, popularly believed to be the continent in which it first

originated and whence it was disseminated to other lands. Whether the outbreak of last year began in Asia is not known, although it is certain that it has raged through that continent and has been the cause of a vast mortality. The November issue of *Practical Medicine*, a publication of Delhi, India, is devoted to a consideration of influenza, and contains some instructive papers contributed by Indian and English medical men. According to Jaibaj Behari, B.Sc., writing on the influenzal type of fever at Lucknow, the first outbreak there in the early summer was mild while the one that was raging at the time of writing was very virulent. Deaths were mainly due to pneumonia which, when both lungs were involved, invariably proved fatal. Col. U. White expressed the opinion that the epidemic was in nearly all respects similar to that of 1890. Dr. W. E. McKechnie, Dr. Prem Nath Sim, and Col. Glen Liston held the same views, but one or two of the native medical men took the stand that it was by no means certain that such was the case, and suggested that it might be pestis pneumonica. Suggestions of this nature have been advanced previously, among others by Capt. J. J. King, M.C., U. S. A., in the MEDICAL RECORD of October 12, and it has been hinted that the influx of Chinese laborers in France may have been the agents by which the disease was conveyed to Europe, and spread. The majority of medical practitioners in India, however, appear to be strongly of the view that this pandemic of influenza resembles in its main characteristics that of 1889-90, and the greater number of medical men in Europe and in this country are of the same opinion. Of course, the type of pneumonia which has proved so fatal is extremely virulent, and is almost sui generis. This has been demonstrated by the pathological findings. Those of Professor John J. Mackenzie of Toronto, which were published in the *Dominion Medical Monthly* for December, 1918, to which we have previously referred, were especially instructive and suggestive. At the same time, there is little support for the view that the present epidemic differs in its essence from previous visitations of influenza.

UNMOTIVATED NERVOUS DYSPEPSIA AND TUBERCULOSIS.

IN a clinical lecture Professor Stahelin recently called attention to the masking of tuberculosis by some unmotivated gastric disorder. In a cited case the latter was expressed as a mild gastritis and the sequence was said to be not uncommon, the stomach disorder preceding the outbreak of tuberculosis. In such cases an *x*-ray unmasks the presence of old foci in the lungs. In an article by Aubertin and Joffe in the *Journal de médecine et de chirurgie pratiques* for December 25, a similar association is referred to. In a military case the first diagnosis was crises of recurrent dyspepsia of indeterminate nature. In this particular subject there was a mitral lesion which added to the symptoms, but certain attacks of dyspnea noted proved to have no connection with the heart's action. So perplexing was the picture that simulation was thought of. The *x*-ray showed a negative picture. Repeated sputum examinations revealed a few tubercle bacilli after several negative tests. A second *x*-ray picture showed suspicious foci in the thorax. The patient was now classed as tuberculous, and the crises of dyspepsia and dyspnea were regarded as of a decided nervous type. The possibility of an organic factor, such as neuritis of the phrenic, was not considered and the manifestations were regarded as purely psychogenic. It is apparent, however, that the case was of the type described by Stahelin. The latter in one case discovered and corrected a ptosis with apparently successful outcome, but tuberculosis rapidly supervened from an explosion of the latent form. These gastric troubles may be compared to the attacks of pseudoinfluenza seen in latent tubercle which will later become manifest.

LATIN AMERICAN CONGRESSES IN FRANCE.

THE first of these congresses was held in 1916 at Lyons, and the second, one year later, at Paris. Finally the third of the series has just been held at Bordeaux. Meanwhile the transactions of the second or Paris Congress of 1917 have been published. The entire movement is one of sympathy for France by Latin Americans and it is intended to cement post-bellum friendships between France on the one hand and Brazil and the Spanish-speaking American States on the other. The entire movement, in other words, is toward a centralization of the Latin races in both hemispheres, largely to oppose Teutonic kultur and practice. The rapprochement concerns particularly the universities, with reciprocity of all kinds, including exchange professors; but signs are not lacking of comity in the direction of commerce and international politics. While the ideals of North America are in agreement with those of Latin America, there is a sort of suppressed note that the Latin races must form a sentiment for self-protection which must not again be abused as the Germans abused it.

News of the Week.

Annual Report of the Surgeon General U. S. Navy.—In his annual report, the Surgeon General points out that the policy during the past year has been to concentrate every effort on the immediate physical needs of the Navy's personnel. This action was rendered all the more necessary by the great increase of personnel due to the war and also to the fact that large numbers of men were collected together, thereby augmenting the opportunities for spreading contagion. It is interesting, therefore, to learn that the percentage of men in the service infected with venereal disease is lower year after year than the percentage of males of corresponding ages in civil life. During the year ended June 30, 1918, the admission rate for venereal diseases, including syphilis, was 105.77, against the average rate of 157.9 for the nine calendar years 1909 to 1917. A part of this very considerable decrease can be attributed to interdiction of alcoholic liquors for men in uniform and the declaration of zones around numerous naval stations. The entire report is satisfactory and deflects much credit on

the Medical Department for the energetic and efficient manner in which its members have coped with the added difficulties of the past two years.

Amendment to Sanitary Code.—At a meeting of the Public Health Council of New York State on December 4, that part of Regulation 36 of Chapter 11 relating to the minimum isolation period for measles was changed to read as follows: "Measles, until at least five days after the appearance of the rash."

University of Pennsylvania Hospital Open to Women.—For the first time in its history the doors of the Hospital of the University of Pennsylvania are to be open to women. Two women students who will graduate in June have been chosen by the managers as internes and will assume their duties upon graduation.

Resolutions on Prohibition Amendment.—At the stated meeting of the Medical Society of the County of New York, on January 27, the following resolutions were introduced by Dr. John P. Davin. "Resolved: That the Medical Society of the County of New York oppose the ratification by the Legislature of New York of the measure now before it for National Prohibition as irrational, unscientific, and in opposition to the accepted usage of all civilized nations throughout the world. and as putting upon the Medical Profession the burden of prescribing and dispensing alcoholic beverages of proven therapeutic worth, while allowing the unlimited sale to the public of patent, proprietary and quack remedies containing alcohol in varying amount without control or hindrance by the officers of the State." In commenting on these resolutions Dr. Davin declared that this was an important question for the consideration of the profession, since there was a matter of health and morals involved, and while as professional men they had nothing to do with the morals part of it, they had a great deal to do with the health part. The use of alcohol in the treatment of pneumonia and other diseases demanded that the physician should not have the handicap imposed by the prohibition amendment. The resolutions were referred to the Committee of Public Health to be reported on at the next meeting.

Enforcing Narcotic Drug Control.—Plans for the enforcement of the law concerning the sale of narcotics have been formulated at a conference of the deputies of the Department of Narcotic Drug Control. The Department intends to have representatives visit every person or institution authorized to possess, dispense, or prescribe habit-forming drugs to ascertain if their records comply with the law, and in the case of violation, to enforce the law and take steps to have the offenders punished. In putting this law into operation the Department of Narcotic Drug Control sent a communication to the Medical Society of New York County, stating that the commission recognized that many narcotic drug problems were administrative, educational, and medical rather than legislative as was most clearly shown by the testimony brought out at a hearing before the Legislative Investigating Commission. The Commission therefore aimed so to administer the law that the honest physician would be hampered as little as possible in the care and treatment of drug addicts and other patients. It was also the purpose of the Commission to administer the law in a spirit of helpfulness to the unfortunate, but with such care and restriction that the growing evil of narcotic drug addiction might be effectually checked. The Commission therefore earnestly requested the cooperation and assistance of the medical societies of the State in its efforts to alleviate suffering and to provide remedy and care for the drug addict. It also asked the cooperation of the societies in restraining certain well-known evils and abuses which existed among some of those legally entitled to possess and dispense narcotic drugs. The Commission invited medical organizations as such and medical men individually to consult freely with the department, asking or offering suggestions or advice.

Gift to Broad Street Hospital.—An anonymous gift of $100,000 has been made to the Broad Street Hospital, New York, with the provision that the balance of $200,000 needed for the erection of the addition to the hospital be raised by March 1, of this year. A number of people interested in the hospital have pledged themselves as a memorial to the late Colonel Theodore Roosevelt to equip and maintain by endowment an elaborate suite of rooms in the new addition when it is erected. Contributions of $60,000 have already been subscribed. This hospital which was opened in September, 1917, with 35 beds found it necessary within three months to enlarge its capacity. During the first twelve months of operation 1,334 patients were admitted to the institution for treatment.

Venereal Disease Bureau Gives Lectures.—The Bureau of Venereal Diseases of the New York State Department of Health has outlined an extensive program on sex education and venereal control which is already under way throughout the State. It is planned to cover the State with an illustrated lecture which will deal with venereal disease problems. Later a campaign of sex education will be conducted for the instruction of parents in order that they may be able to instruct their children properly. While thus far lectures have been given largely to men only, it is planned to speak to mixed audiences and to mothers' clubs at a later date. Although the State will eventually be entirely covered by this program, the Department is especially desirous of getting in touch with any community which may feel the immediate necessity for a lecture of this sort and will be glad to supply an illustrated talk on a few days' notice.

Dr. Harry Friedenwald of New York City has been named medical adviser to the American Zionist Medical Unit, which is now in Palestine. and has sailed to join the unit in that country.

Plan for National Health Campaign.—At a meeting in the Municipal Building, New York, on February 1, of representatives of the American Red Cross and of the Community Councils of National Defense, plans were discussed for cooperation in carrying out the proposed health program of the Red Cross. The plan proposed is based on the idea that health being a social prob-

lem should be handled by the community as a whole, and that every citizen able to do public service is to be systematically enrolled in whatever capacity he is best fitted to work.

Skin Disease Epidemic in Paris.—A despatch from Paris to the New York *Sun* states that an annoying skin affection, something like the "seven years itch," is particularly in evidence in that city, having been brought there by soldiers returning from the battlefront. The parasite is said to be rampant at the headquarters of the American Mission.

New York Health Department Extends Work.—On the invitation of Health Commissioner Copeland, representatives of the Labor Sanitation Conference met him and conferred regarding the extension of the work of industrial hygiene. It was suggested that the work of the department be extended to fields of industry not heretofore included, such as stonecutters and marble cutters, sheet-metal workers, lithographers, printers, painters, and the shipbuilding industry. Dr. Copeland announced that the Board of Estimate had consented to make available at once the money for this work and that he would appoint ten temporary medical inspectors, and fifteen or twenty sanitary inspectors to begin the work immediately.

Motor Fatalities in New York.—The report of the National Highways Protective Society for the month of January shows that 49 persons lost their lives as the result of automobile accidents during the month. In New York State outside of New York City 19 were killed by automobiles and three by trolleys. The total number of street accidents in New York City was 58, the highest fatality figure yet recorded for January. In New Jersey 17 were killed by automobiles, four by trolleys, and two by wagons. Figures compiled for the year 1918 show an increase of fatalities from automobile accidents of 30 per cent. over 1917, with 1,189 fatalities for 1918 against 837 for 1917. An estimate of the economic loss through lives thus crushed out, on a basis of $10,000, the value the Federal authorities have fixed on a soldier's life, is $11,890,000.

Bill to Make State Sell Milk.—An amendment has been framed for introduction into the New York State Legislature to the Costillo bill, aimed at the producers' distributors' milk trust, which provides for a State commission which shall be clothed with authority to spend $250,000 or more yearly to establish agencies to sell milk at a fair price.

Addition to Volunteer Hospital.—An addition to the Volunteer Hospital, New York, consisting of four stories and a solarium to cost $175,000, is in the process of construction. This extension is in line with the original plans of the hospital but was temporarily abandoned because of war conditions. Last year the hospital gave 38,000 treatments to 14,000 patients and answered 4,000 ambulance calls.

Clinical Society of the Hospital for Deformities and Joint Diseases.—A meeting will be held at 41 East 123d Street on Tuesday net at 8:30 P. M. Papers will be read by Drs. Frauenthal, Kilmer, Michel and Rodman.

Charitable Bequests.—The will of the late Benjamin Blumenthal makes the following bequests: Mt. Sinai Hospital, New York, $15,000; Lebanon Hospital, $5,000; Hebrew Orphan Asylum, United Hebrew Charities, Home for Aged and Infirm Hebrews, and Hebrew Infant Asylum, $10,000 each; St. Vincent's and the Presbyterian Hospitals, and the Sanitarium for Hebrew Children, $2,500 each.

The will of the late Henry Joseph Duveen makes bequests of $5,000 to Mt. Sinai and the Woman's Hospitals, New York, and the Middlesex Hospital, London.

The will of the late Dr. William Mecklenburg Polk, whose estate was recently appraised at $875,121, makes a bequest of $5,000 to Cornell University.

Sir Arthur Pearson, who has come to this country for the purpose of assisting in the reeducation of American soldiers blinded in the war, was the guest of honor at a farewell dinner given in the Ritz-Carlton Hotel, New York, on January 31, by Dr. Schuller Skaats Wheeler.

Professors Alonzo Taylor and Vernon Kellogg are making a railroad journey across Germany to supervise the relief work that has just been established at Danzig. They have in their charge 10,000 cans of condensed milk for Poland. The care of a consignment of such a scarce article as milk across Germany at the present time is said to be a very hazardous undertaking.

Police Hospital Planned.—Police Commissioner Enright of New York is undertaking to build a $5,000,000 hospital for policemen and their families and for other persons who would otherwise not receive hospital attention. A campaign to raise the funds required is to be started in the course of a week or two.

Columbia University May Control Hospital.—It is reported that arrangements are under discussion regarding a plan for cooperation between the College of Physicians and Surgeons of Columbia University and the Lenox Hill Hospital. Details will probably not be made public until after the meeting of the trustees of the university in March.

Appeal for Nurses.—An appeal has been sent out from Henry Street Settlement, New York, for nurses and for money to bring nurses to the city to aid in the fight against pneumonia and influenza. The settlement's nurses have been caring for 2,000 patients a day and that is all they have been able to do. During the epidemic 189 nurses and 50 nurses' aids cared for 4,000 cases a day. On learning of this appeal Health Commissioner Copeland announced that the Health Department had from 400 to 500 nurses that could aid in this work and asks that cases for which care cannot be provided be referred to the Health Department.

The American Congress of Physicians and Surgeons will be held in Atlantic City, June 16-18, 1919. The change from Washington was determined upon because of the uncertainty in regard to hotel accommodations at Washington.

Medical Society Elections.—The NEW HAVEN (CONN.) MEDICAL ASSOCIATION, at its annual meeting held Jan. 15, elected the following officers for the ensuing year: *President*, Dr. L. M. Gompertz; *Vice-President*, Dr. R. E. Peck; *Recording Secretary*, Dr.

F. E. Phillips; *Financial Secretary,* Dr. S. J. Goldberg; *Treasurer,* Dr. F. H. Wheeler.

The New London (Conn.) Medical Society, at its annual meeting held Jan. 17, 1919, elected the following officers for the ensuing year: *President,* Dr. Joseph M. Ganey; *Vice-President,* Dr. Charles G. Barnum; *Secretary and Treasurer,* Dr. Ross E. Black.

The New Britain (Conn.) Medical Society, at its annual meeting, January 8, 1919, elected the following officers for the ensuing year: *President,* Dr. E. J. Dray; *Vice-President,* Dr. Robinson; *Secretary and Treasurer,* Dr. Mann.

The Spokane County (Wash.) Medical Society, at its annual meeting elected the following officers for the ensuing year: *President,* Dr. A. A. Matthews; *First Vice-President,* Dr. A. T. R. Cunningham; *Second Vice-President,* Dr. J. M. Gunning; *Third Vice-President,* Dr. E. H. Northrup; *Corresponding Secretary,* Dr. Carroll Smith; *Recording Secretary,* Dr. E. J. M. Lawrence; *Treasurer,* Dr. Sidney Oppenheimer.

The Kings County Medical Society, at its annual meeting, held in Brooklyn, December 17, 1918, elected the following officers for the ensuing year: *President,* Dr. Stephen H. Lutz; *First Vice-President,* Dr. R. L. Moorehead; *Second Vice-President,* Dr. John A. Lee; *Secretary,* Dr. Charles E. Schofield; *Treasurer,* Dr. Alfred Bell.

The Queens-Nassau (L. I.) Medical Society, at its annual meeting in Brooklyn recently, elected the following officers for the ensuing year: *President,* Dr. Howard L. Moss, Richmond Hill; *Vice-President,* Dr. Arthur D. Jaques, Lynbrook; *Secretary-Treasurer,* Dr. James S. Cooley, Mineola.

Obituary Notes.—Dr. George Newton Ferris of Brooklyn, N. Y., died of heart disease at the residence of a relative in that city, on January 28, aged 64 years. He was a graduate of the Long Island College Hospital, in 1879, and from 1881 to 1889 superintendent of the Kings County Hospital.

Dr. Clarence J. Blake, emeritus professor of otology at the Harvard University Medical School, died at his home in Boston, on January 29, aged 76 years. He was a graduate of the Harvard Medical School, in 1865, from 1870 to 1875 lecturer at Harvard, and from 1875 to 1888 instructor; he then became professor of otology.

Dr. Samuel H. Robertson of Princess Anne, Md., who retired from the active practice of medicine about fifteen years ago, died at his home, on January 21, aged 88 years.

Dr. Edward Sanders, a graduate of the New York University Medical College, in 1876, and attending physician to the Hebrew Orphan Asylum, died at his home in New York City on January 29.

Dr. Henry Griswold, a graduate of the Louisville, Ky., Medical College, in 1864, a member of the American Medical Association and the New York Academy of Medicine, died at his home in New York on February 1, aged 76 years.

Dr. Frank Blaisdell died at his home in Keene, N. H., on January 17, aged 66 years. He was graduated from Dartmouth Medical College, in 1876, was at one time president of the New Hampshire Medical Association, and served on the board of physicians and surgeons of the Elliot Hospital in Manchester.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, January 10, 1919.

Demobilization of the Medical Profession.—A conference has been held between representatives of the Central Medical War Committee and other bodies interested in the demobilization and resettlement of doctors. Deputations have been sent by the Committee to the Ministry of Labor on the same subject. From a great deal of thought mostly well directed, a scheme has now evolved, though what is actually done will depend also upon the actions of other Government Departments. Just before Christmas the National Insurance Commissioners sent a circular letter to each Insurance Committee in England dealing with the subject, while a letter in similar terms was issued by the Welsh Insurance Commissioners to each Insurance Committee in Wales. The letter to the Committees pointed out that a substantial number of medical men were required to meet the urgent needs of the civil population in those areas in which a breakdown of medical service appeared imminent or might at any rate be feared during the winter months. The National Insurance Commissioners, it is true, anticipated that the men already released, together with those under orders to return would meet the more urgent needs, but they considered the question of how to reestablish at the earliest date at which military exigencies would permit, an adequate health service, was one that should be answered at once. At what standard such reestablishment should aim presents some difficulty. The increasing shortage of doctors in civil practice during the greater part of the period covered by the war precluded the statutory scheme of medical benefits to insured persons from being maintained at its normal, and undoubtedly, despite large annual exchequer grants paid towards the cost of medical remuneration under the National Insurance Acts, many complaints of inadequate attendance and improper medical certification have been justified. The rights of insured persons have been curtailed, and although this may be regarded as a necessary sequence of war conditions, it is felt that the position should be remedied at the earliest opportunity, for, after all, the matter is one which concerns directly or indirectly 30 per cent. of the population. The National Insurance Commissioners upon these grounds approached the Ministry of National Service, with the result that that Ministry agreed to secure priority for the release of medical men who are prepared to resume their old practices under the National Insurance Acts or to take up new practices in the districts where such assistance was particularly required. The result has been definite instruction from the Ministry of National Service to each Insurance Committee in England and Wales to review the medical situation in their areas, district by district, and to report in detail on the following points: Approximate number of the population and the nature of the country and its road and rail communications; *Cadre* of local doctors doing insurance work before the war or ready to do it now, with any

special information as to their qualities; methods of restoring the service to efficiency where it seems clear that importation of new doctors, engagement of partners, and so on, are required. These detailed reports are to be sent in without delay, and the hope is expressed that the doctors themselves will assist in the drawing up of the reports, a personal request of this nature having been addressed to medical men. In this request special attention is drawn to the question of the adequacy or inadequacy of the insurance service in the locality, and the doctor is asked to advise his Insurance Committee if he requires any measure of relief owing to the work that will presently fall upon him. The net result is that the National Commissioners are anxious to get the Insurance Committees and the Panel doctors into agreement on the fairest and readiest ways of restoring Panel practice to its proper state of efficiency.

In the meantime the Central Medical War Committee has drawn up a scheme for demobilization which deals with the question of priority of release on personal and professional grounds of all medical officers serving temporarily with the Forces. The scheme has received the approval of the Ministry of National Service and runs as follows:

Part I.

MEN OVER THIRTY YEARS OF AGE AT DATE OF ARMISTICE—VIZ., MEN BORN ON OR BEFORE NOVEMBER 11, 1888.

I. The following points will be awarded on the grounds of length of service and age:

Men Mobilized at the Outbreak of War (*e.g.* R.N.V.R., R N.R., R A. M.C.(T.), and R.A.M.C.	Points.
Over 45	30
40-45	29
35-40	28
30-35	27

Men with Over Three Years' Service.	Points.
Over 45	26
40-45	25
35-40	24
30-35	23

Men with Over Two Years' Service.	Points.
Over 45	22
40-45	21
35-40	20
30-35	19

Men with One Year's Service.	Points.
Over 45	18
40-45	17
35-40	16
30-35	15

Men with Less Than One Year's Service.	Points.
Over 45	14
40-45	13
35-40	12
30-35	11

II. The following points will be added or subtracted in respect of the following modifying conditions:

	Points.
(1) If in whole-time salaried post, subtract	6
(2) If with no paid appointment or N.H.I. work, add	3
(3) If in single-handed practice, add	3
(4) If all members of partnership are on service, and no member of the partnership is otherwise entitled to more than — points, add, in case of one partner	4
(5) If married, add	4
(6) If dependents, children or otherwise. 1 point for each dependent up to a maximum of	4

III. Additional points may be awarded in respect of financial or other circumstances of an exceptional character which justify a claim to a higher order of priority than that determined by the foregoing provisions. The award of any such additional points would be the subject of special assessment by the committee, and any man who deems that he has suffered special hardship on such grounds should apply to the committee for a special consideration of his case on the facts.

IV. The order of priority of men of thirty and over shall be according to the net number of points accruing to each man under this part of the scheme, men with a greater number of points ranking before men with a less number of points.

Part II.

MEN UNDER THIRTY YEARS OF AGE AT DATE OF ARMISTICE—VIZ., MEN BORN AFTER NOVEMBER 11, 1888.

V. The order of priority determined under Part II shall be in continuation of the order of priority determined under Part I.

VI. The order of priority of men under thirty years at date of the armistice shall be according to their age, the older before the younger; no priority being, however. accorded as between men born in any one calendar year:

Provided that, in the event of the Central Medical War Committee deciding upon a special application, that financial or other circumstances exist of an exceptional character which justify a claim by the applicant to a higher order of priority than that accorded under the foregoing provisions, the committee may award that the applicant should be classed either on a level of priority (under Part II) with men born in a specified earlier calendar year, or on a level of priority with men entitled to a specified number of points (under Part I).

The main object, it will be seen, has been to devise a plan which is at once simple, capable of amendment at any time, and easily explained to those concerned. As soon as provision is made for areas in which the medical service has been dangerously depleted, demobilization of medical officers will proceed briskly. It will be seen that special claims on financial and other personal grounds will not be taken into account in the method of classification, but such claims can be submitted to the Central Medical War Committee for special assessment.

There is an obviously different point of view in the proposals of the Central Medical War Committee and those of the National Insurance Commissioners and the Ministry of National Service. The government departments are concerned with getting back the doctors previously employed in public services or in private practice, while the Central Medical War Committee, as the body which recruited most of the temporary medical officers for the army, is especially anxious that decommissioning should follow in fairness the lines dictated by the individual urgency of cases.

The Treatment of Rabies in England.—The outbreak of rabies in Cornwall and Devonshire, which, without being exactly serious, has none the less been of considerable duration, has been made the subject of official memorandum lately by the Local Government Board, from which the interesting fact appears that, under the ægis of the Board, a Pasteur center for treatment has been set up at Plymouth. It is understood that about thirty persons have actually been bitten by dogs definitely ascertained to be rabid since the outbreak was discovered, and the first series of these patients were sent to Paris under elaborate arrangements to be treated by Professor Emil Roux at the Pasteur Institute. But, it being practicable, in Professor Roux's opinion, to rely upon preservatives—cold and glycerin—to maintain the virus at a proper degree of potency for some weeks, the Local Government Board decided to conduct the antirabic technique on this side of the Channel. The Pasteur Institute has accordingly consented to supply to a center at Plymouth spinal cords representing fixed virus of different ages, from which emulsions can be prepared and treatment administered on lines exactly corresponding with those followed in Paris. All the organization has been placed under the su-

perintendence of Dr. Pethybridge, pathologist of the South Devon and East Cornwall Hospital. District Councils, acting under the direction of the Local Government Board, pays reasonable sums for the maintenance in Plymouth of persons requiring treatment, and who cannot afford the expense of the sojourn at an expensive port, for the treatment is spread over a course of three weeks. This provision of antirabic treatment in England is very wise, while rabies is known to exist in France, for during demobilization no effective blockade can be established for certain.

The Great Men of the Seventies.—The occurrence in the British medical press during the first week of the new year of obituary notices of Sir William Dalby, the famous aural surgeon, and Dr. Thomas Buzzard, the equally famous neurologist, point the way to certain reflections on the position of the medical men who reached the zenith of their fame at the beginning of the last quarter of the Nineteenth Century. Between the years 1875 and 1885—the dates might be for purposes of argument extended in both directions—the doctrines of aseptic surgery were received, revised, perfected, and accepted, and thereupon, through bacteriology, the whole foundations of surgery and medicine were reconsidered. Clinical experience as well as the teachings of physics and biology had given to medicine both a stable foundation and a vast record of pathological pictures equally stable; but, on the one hand, the meaning of those pictures was now incalculably enlarged, and, on the other, a door was opened for such an extension of clinical practice that the experience of the past could be no comprehensive guide to the procedure of the future. What was the position of, for example, men like Timothy Homes in surgery and Russell Reynolds in medicine, of Dalby and Buzzard and a very large list of distinguished men who have died, at ages varying from 60 to 80, during the last 25 years? The great revolution found them at the top of their fame. Homes, for example, was the editor of the classical symposium of surgery, Reynolds was the editor of an inclusive dictionary of medicine, and their names were typical of contemporary wisdom. Suddenly contemporary wisdom was seen to be still wisdom but very partial wisdom and equally suddenly undreamed of developments in the clinical side of pathological medicine and surgery passed into easily realizable possibilities. Obviously the position of these clinical leaders was to some extent what they could make of it. Some were flexible enough to learn the meaning of the new wisdom and to become students while they were still leaders, associating themselves with what was to come. Others marked time and were content to be links between the past and the future. A few, a very few, were recalcitrant. Buzzard belonged to the flexible type, Dalby to the more conservative, but both were far too great not to recognize that the new was a vast improvement on the old and held out promises of untold good for the science of medicine. Sir William Dalby was a great aural surgeon at a time when cranial surgery was in its infancy and when such procedure as the complete mastoid operation was attended with huge risks. He decided not to relearn operative surgery, while without it he could still be of great use to a large range of patients, so he promptly associated himself with younger otologists, by consultation with whom he was able to secure for his patients that operative interference which he declined himself to give them. His general teaching on the diagnosis and treatment of the deaf remained sound, while one special piece of work which he initiated in England came to fruition under his care. It was Dalby who introduced into England the method of lip-reading whereby he provided for thousands of born-deaf children the opportunity of becoming happy, normal, and efficient citizens. Buzzard was more progressive. He realized that in bacteriology we might have the clue to the mastery of many nervous diseases. Originally mainly interested in hysteria, hypochondriasis, and the tics, he used the clinical material provided for him at the National Hospital for Paralysis and Epilepsy to popularize the doctrine that microorganisms and their toxins would be found to have a basic influence in the production of diseases of the nervous system; and, while whole generations of younger workers have achieved practical results along the lines of what was then largely a theory, to Buzzard there accrues the credit of having promulgated and started the theory, and to that extent of having inspired the future work. Sufficient credit is not given in this country to the work of the great men of the seventies placed embarrassingly between the new learning and the old, too habituated to lead to make it easy to follow. During twenty years it was their lot to hold the fort of established learning against too rapid and violent reformers; and it was also their duty to admit that the new teaching was both right and in no sense a derivative of the old.

6. Empyema, Abscess, and Gangrene of the Lung Following Epidemic Influenza.—Moses Behrend gives the results obtained by resection of the ribs in 19 cases of empyema, abscess and gangrene of the lung following epidemic influenza. The diagnosis of these cases presents many difficulties. The distinguishing feature, however, in abscess of the lung was found to be the dullness in a localized area, whereas in the large empyemas the entire chest was flat, usually posteriorly and involving the axillary region. Another distinguishing feature was that in abscess of the lung breath sounds could be heard about the entire involved area, while in large frank empyemas breath sounds and tactile fremitus as a rule were entirely absent. It must be remembered, however, that all breath sounds heard over a pneumonia may be elicited over an empyema, the one outstanding factor being the prolongation of symptoms and physical signs beyond the period allotted to a pneumonia. These difficulties of diagnosis may be largely overcome by the use of the aspirator or Luer Syringe. The aspirator is the better instrument and, in the author's opinion, it is not used often enough; it can

do no harm if used in an aseptic manner and even a dry tap has been followed by good results. The *x*-ray may be of service in locating the fluid, but in the author's cases the *x*-ray was incorrect in a number of instances. The operation of choice is resection of the ribs. This procedure permits of an operative diagnosis differentiating between an empyema and a lesion of the lung. Thorough drainage is instituted, which cannot be obtained by any other method. In infants and children up to two years of age, thoracotomy may be done, but from the surgeon's point of view this is at best an inefficient operation. There is no objection to aspiration before operation. It cannot be curative, but it is beneficial since it allows for expansion of the lungs by equalizing the pressure within the thorax before the ribs are excised.

3. Ventricular Drainage by Puncture of the Corpus Callosum in Acute Obstructive Hydrocephalus Due to Cerebrospinal Meningitis.—De Witt Stetten and Dudley Roberts report a case of epidemic cerebrospinal meningitis which, after running a relatively normal course, rather suddenly developed signs and symptoms pointing to an acute obstructive hydrocephalus. As the condition of the patient was extremely critical, being little short of moribund, it was decided to establish ventricular drainage by puncture of the corpus callosum. This was done some ten days after admission to the hospital, the patient being in a raving delirium. About 25 c.c. of very slightly turbid, blood-stained fluid was obtained, which was entirely different in character to the fluid obtained by lumbar puncture four hours previously, when 40 c.c. of cloudy fluid were withdrawn. Diagnosis of ventricular block was conclusively proved by the manner in which the fluid gushed from the cannula. Examination of this fluid showed no evidence of active meningococcic inflammation with the ventricles. The immediate postoperative improvement in the patient was almost miraculous. Subsidence of the protruding intracranial contents shortly after operation, as the patient's condition improved, corroborated the view that recovery, which eventually became complete, was due to the relief of the ventricular distension. The authors feel justified in advocating puncture of the corpus callosum for ventricular drainage as a rational, life saving procedure when the clinical picture of ventricular obstruction observed in the case in question appears in the course of a cerebrospinal meningitis. If, in addition to ventricular blocking, there appears to be actual infection of the ventricle—turbid or purulent fluid or isolation of diplococci—intraventricular administration of antimeningitis serum should be combined with puncture of the corpus callosum. Care must be taken to inject less fluid into the ventricles than the amount of fluid withdrawn.

5. Effect of Cardiac Distress on the Work of Recruits.—Lieut. Gordon E. Hein contributes the results of observations on 300 men returned to the development battalion from various line organizations because of complaints of "heart trouble." The largest proportion of these cases occurred among farmers and laborers, the next largest group being that of clerks. With exception of measles and whooping cough, acute rheumatic fever was the most common illness. The conclusions drawn from this series of cases are: (1) That few organic valvular heart lesions escape during the routine examination of recruits. (2) That men with persistent tachycardia due to various causes form the largest group slipping by the examiners, later to return unable to perform full military duty. (3) That the number of alcohol and tobacco users among those complaining of cardiac distress seems high. Sedentary occupation seemed to have little to do with the cases examined. (4) A large number of men with enlarged thyroid glands develop cardiac symptoms when put under severe physical strain. Soldiers with enlarged thyroid glands should be kept under observation. (5) A certain percentage of the persistent tachycardias are fundamentally nervous conditions and can be eliminated by the neuropsychiatrists. (6) The persistent tachycardias are a group of conditions, the etiology of which must be determined before a rational plan of treatment can be prescribed.

1. Observations on the Severe Anemias of Pregnancy and the Postpartum State.—Sir William Osler divides these cases into four groups: (1) Anemia from postpartum hemorrhage. Two types may be seen—(a) Those in which bleeding is profuse and rapidly fatal; everything may have gone well and the doctor may have left, feeling that all was satisfactory; patient suddenly becomes restless, there is pallor, and dressings are found to be soaked with blood; symptoms soon become those of acute anemia, with convulsions and sudden collapse. (b) Those in which anemia follows repeated small hemorrhages, not infrequently after abortion and more rarely after delivery at term; the general appearance may be that of an ordinary Addisonian anemia. (2) The severe anemia of pregnancy. Although Channing and Lebert recognized that the so-called chloro-anemia of pregnancy might pass on to a grave and fatal form, it was the publication of Gusserow's five fatal cases that drew the attention of the profession to the seriousness of severe anemia in pregnancy. (3) Postpartum anemia. After a normal delivery without excessive loss of blood, the patient begins to get pale; within a few weeks the blood count may fall below 2,000,000 per c.mm. and the anemia prove fatal in from 8 to 12 weeks. Clinically this form is indistinguishable from true Addisonian anemia except as regards absence of recurrence. The presence of continuous fever may lead to error in diagnosis and even suggest typhoid fever; or the fever may be associated with chills and suggest malaria. (4) The acute anemia of postpartum sepsis. In no condition is there such rapid hemolysis as in postpartum sepsis, a form of anemia not sufficiently recognized or studied. In acute endocarditis the anemia with a large spleen may completely mask the clinical picture, as in the cases reported by the author in 1913. Such cases may be rapidly fatal and, as an example, the following case is cited: Blood loss at delivery was not severe; patient was seen hy author on the seventh day, when in a state of profound anemia; there had been an unusually foul but slight discharge for some days; red blood cells were 1,000,000 per c.mm. and leucocytes 20,000. Chief complaint was throbbing of aorta. Death occurred on the twelfth day. There was diphtheritic

endometritis, septic thrombi in pelvic veins; no endocarditis. Commenting on these cases Sir William Osler remarks that as yet there is no clue to the nature of the hemolytic agent involved. This agent differs in one all-important particular from that which causes the anemia of Addison, since, when recovery takes place, it is permanent and the woman may escape in subsequent pregnancies. In one of the author's cases the patient, after recovery from a severe attack, bore two children and was well thirty years after the attack. In the hands of skilful students the blood picture should be of value in prognosis. Signs of active regeneration are present, indicated by blood crises and a large proportion of red cells with signs of recent formation, basophilic granulation, mitochondria, and reticulation. The number may rise from 1 to 20 to 25 per cent., with marked bone marrow stimulation. A high color index is the rule in pregnancy and postpartum cases. Absence of platelets is a feature of the common idiopathic anemia in contrast to the posthemorrhagic and septic forms. Osler states that his experience is exceptional and much more hopeful than is indicated in the literature, and particularly in works on obstetrics. From records of other observers and from his personal experience he believes that the danger of a grave anemia, progressive in character, is not great after fairly profuse hemorrhage. On the other hand, repeated small losses of blood after abortion or normal delivery may be followed by an anemia out of all proportion to the quantity of blood lost. In some cases the starting point of Addison's anemia seems to be repeated epistaxis or bleeding piles. Treatment indicated is fresh air, rest, food, iron, arsenic, and transfusion if required. In regard to the latter, though the newer technique has many advantages, in Addison's anemia the results do not appear to be more favorable than with the Aveling or Roussel apparatus.

1. **Pan American Scientific Interchange.**—Fernandez replies to those who want to have the expansion of Latin America in conjunction with Spain, and in a way against the United States. Fernandez justly claims that all or mostly all the Latin American countries should be in favor of scientific interchange with North America. The small Republics of Latin America had hoped that the mother country (Spain) would have come back to her ancient heroic times and fought side by side with them in the titanic struggle against Teuton militarism, and they were dismayed when instead of that, they saw that Spain was arm in arm with the war lords of Germany and did not criticize such barbaric acts as the sinking of the Lusitania, the murder of Edith Cavell, and the wanton destruction of scientific and historic monuments. Now it is too late to invoke blood attachments that will, however, never be forgotten, but in the future, the scientific guidance of most of the Latin American countries, and especially that of Cuba, will be in her great free neighbor to the north.

The Clinical Picture of Suprarenal Apoplexy.—K. Löwenthal has met with a case of double pneumonia and pleural collection which was followed by the following clinical syndrome: intense abdominal pain, constipation and slight meteorism, profuse sudation, normal temperature and a slow, irregular pulse. At autopsy the writer found a hemorrhage in both suprarenals; the medullary substance was entirely destroyed in one, and greatly involved in the other. The cortex of the glands was preserved. The writer points out the concordance between the clinical signs offered and the physiological data known, which show that the disturbances arising in this case resulted from a lack of tonus of the sympathetic, that is to say, from an adrenalin insufficiency. The differential diagnosis from ileus or peritonitis should be based above all on the pulse, which in these circumstances is rapid, while in suprarenal apoplexy there is a tendency to slowing of the pulse rate. In the case reported by the writer there were 44 beats to the minute.

The Influence of the Thymus Gland on Regeneration of Bone After a Traumata.—K. Glaesner has carried out the following experimental work. Young rabbits belonging to the same litter were each trephined on the tibia. Some of the animals were fed on thymus gland, the others serving as control animals. The evolution of the bone trauma in each was controlled by regularly repeated radiographic examinations. The writer concludes that the exhibition of thymus gland hastens regeneration of bone traumata. At a given time in repair the difference consisted in the presence of a smaller bone defect, a normal osseous configuration and a moderate callus, while the control animals offered an inverse condition.

The Value of Provocative Injection of Adrenalin in Latent Malaria.—A. Schittenhelm and H. Schlecht remark that among the various procedures proposed for bringing out latent malaria that of adrenalin is the most constant in results, and they do not hesitate to recommend it for general use. In cases offering an uncertain clinical picture but giving rise to a suspicion of latent malaria, the patients are first of all placed under observation for their temperature, combined with repeated blood examination. Following an injection of one milligram of adrenalin when the result is positive there is a rise of temperature and at the same time the plasmodium appears in the blood. The effect of the injection is not always immediate and several days may be required before it manifests itself. It may also happen that the first injection remains negative but positive results are obtained after a second. The writers estimate that the procedure results in positive findings in 90 per cent. of the cases, but a negative result does not eliminate the possibility of a latent malaria being present. No complications are met with from its use.

Kypho-Scoliosis in Tetanus.—E. Becher has observed a soldier who developed tetanus three months after the receipt of his injury. The affection lasted two weeks and was followed by a contracture of the vertebral muscles which lasted for several weeks. A kyphoscoliosis resulted, the patient's height decreasing six centimeters. The contracture was lessened by intramuscular injections of novocain, while adrenalin appeared to increase it. The contracture was not overcome under deep narcosis. Radiography showed a regular incurvation of the spine without any decrease in size or sinking of the vertebræ.

The Formation of Gibbosities in Tetanus.—Eberstadt records a case similar to the above. During the evolution of a chronic tetanus a gobbosity progressively developed. The patient died two months after the development of the tetanus and autopsy revealed a gibbus resulting from compression of the fourth vertebra and flattening of the third and fifth vertebræ. The deformity was not the result of any pathologic process. There were no traces of syphilis or tuberculosis. The writer concludes in favor of a direct action of the tetanic toxin

on the vertebræ to which a permanent spasm of the spinal muscles became added from which the deformity resulted.

Serum Treatment of Influenzal Pneumonia.—U. Friedemann has employed a polyvalent antipneumostreptococcal serum in twenty cases of influenzal pneumonia. Of these twenty cases thirteen would have been very serious or even fatal if they had been treated by ordinary methods. In reference to the results obtained five cases are to be eliminated, as death occurred on the day the first injection was given, while two others died in spite of the injections. In six other cases the results were favorable. The writer insists particularly on the remarkable sedation of the symptoms and remarks that the effect of the serum was "surprising and sudden." In seven other cases the effect was good, although not so evident as in the six cases referred to. The treatment consisted on an intramuscular injection of 50 cc. of the serum in two successive days.

A Case of Varioliform Hemorrhagic Exanthema During Pneumonia.—O. Löwy reports the case of an Italian prisoner who developed a suppurating pneumonia and on the ninth day of the process presented a pustular eruption with umbilicated vesicles, some of which were hemorrhagic. Post mortem examination of the pustules showed a hemorrhage in the chorion, while some of the pustules were found to be formed by intraepidermic cavities. Bacteriological examination revealed the pneumococcus.

Comparative Mortality from Typhus Fever Among a Christian and a Jew Population.—E. Marsini states that the Jewish race has been supposed to possess a lesser receptivity for typhus fever and offers statistical tables derived from his personal experience of 1164 cases. He concludes that Jews offer a greater resistance to the disease than Christians. On the other hand, in the two races the women offered a much smaller mortality than males. In order to explain these facts the writer suggests that the Jews often have the disease in infancy when typhus is much less fatal. On the other hand, women come under medical treatment sooner than men, which increases the possibility of recovery.

The Pandemic in France and Spain.—Maranon, Pittaluga and Ruiz Falco devote an important analytical study to this subject. Not until the end of September did the epidemic of Spain begin to show extreme malignancy through bronchopneumonic complications. Not until then did the lay press begin to agitate the view that the disease was not influenza but some one of the great malignant plagues. An investigation showed that absolutely no difference existed between the French and the Spanish outbreaks. The parallel was complete in every detail. The superior mortality in women was attributed to indoor life and less pure air than that breathed by men. The earliest cases of bronchopneumonia with their extreme virulence had caused suspicion of typhus or the lung pest. The suspicion of cholera came from cases of abdominal type. Every syndrome, every unusual behavior, every rare complication noted in Spain had its counterpart in France. The bacteriology of the disease in the two countries was no less identical. The theory of a filtrable virus has supporters in both countries. The pneumonoseptic type was isolated in both as was also one due to activities of the streptococcus hemolyticus. Pneumo- and streptococci were at times associated in the same case. Upon such a background the pathogenicity of Pfeiffer's bacillus makes a relatively weak showing. This germ per se has never caused a high death rate in the white race, although able to devastate some of the darker races, who are often doomed in advance by its discovery in the secretions. The question of filtrable virus or the germ of Pfeiffer as the initial cause is as yet unsettled, the latter having the prestige of the pandemic of 1889 behind it. One or the other must pave the way for the lethal action of the familiar cocci. To cite a few statistics the number of deaths in Paris from October 3-10 was 1445; from October 10-17 it was 1944. The normal mortality was almost trebled. Nearly half these deaths were imputed to the epidemic. Corresponding figures for Spain are difficult to obtain. Figures for the large cities in the North of Italy are analogous to those of Paris in suggesting three fold the normal mortality.

Aplastic Anemia.—Willebrand describes completely two cases of aplastic anemia of the cryptogenetic type. Such cases would be placed by most authors under subdivisions of pernicious anemia. He further describes briefly 14 other cases from literature which belong in the same category as his own. He then proceeds to analyze the combined 16 cases. The course and symptoms are depicted as well as the finds concerning the blood making organs. There are points of resemblance as well as of difference between the author's type and typical Biermer's anemia. Aplastic anemia is a rare affection and one of great interest because the hematology throws much light on the subject of anemia in general. There is some evidence that the materies morbi of aplastic anemia is identical with that of Biermer's anemia. The points of difference could be explained by the operation of secondary factors. A study of the 16 cases shows that the prognosis is of the worst and that death comes about in from 18 months to 2 years. In that sense the disease is entitled to be included in the pernicious anemias. In fact, it is even more pernicious than many cases which go under that name. The treatment is naturally identical but there is no example of any temporary benefit. The arsenicals exert no influence over the affection. Blood transfusion was practised in four cases, but the benefits were quite insignificant.

Data on the Feeding of the Vienna Population.—A. Durig, in his inaugural lecture delivered on Oct. 31, gives estimates and statistics on the feeding conditions of the Austrian population during the preceding year. The general picture is that of a rapidly progressing famine, as much by the reduced number of calories as by the limited albumin intake, so that the population has undergone a prolonged inanition. The loss of weight has reached as much as eighty pounds in some cases.

Wiener medizinische Wochenschrift.

November 9, 1918.

This issue is devoted to papers on influenza by von Wiesner, Erdheim, Böhm, von Ortner, Götze, and Knöpfelmacher, who offer little that is new. However, the following statistical data may be worth while recording. Females represent 75 per cent. of the fatal cases and 95 per cent. of pneumonias of the suppurating types. Childhood seems more predisposed to this complication, while nephritis, endocarditis, meningitis and pyemia are very uncommon at this age. Domestic servants offer the largest number of cases among all the professions. Among the fatal cases in women 23 per cent. were pregnant. Deaths occur more commonly between the ages of 20 and 30 years, after which come the decades of 10 to 20 and 30 to 40 years. Of the fatal cases 85 per cent. were between the ages of 17 and 40 years. One writer estimates that up to Oct. 18, 1918, the total morbidity of the population was 5.6 per cent.

Rubber Shortage in Germany.—The use of automobiles and bicycles for unessential purposes is interdicted and tires of metal spring are substituted for rubber. Rubber nipples are made in smaller sizes and are also replaced by glass, etc. Synthetic rubber is in use and new processes for rubber regeneration.—*La Presse Médicale.*

Book Reviews.

HYGIENE OF THE EYE. By WM. CAMPBELL POSEY, A.B., M.D.; Ophthalmic Surgeon to the Wills and Howard Hospitals; Professor of Diseases of the Eye in the Philadelphia Polyclinic; Ophthalmologist to the Department of Physical Education of the University of Pennsylvania; Chairman of the Commission on Conservation of Vision of Pennsylvania. 120 illustrations. Price, $4.00. Philadelphia and London: J. B. Lippincott Company, 1918.

THE war has brought the question of sight into special prominence and has focussed the attention of the general public upon the importance of treating eye affections scientifically. Injuries to the eye have increased in proportion as foundries and factories have increased, and it is essential that knowledge should be diffused and carried into effect with regard to preventive measures. In "Hygiene of the Eye" Dr. W. Campbell Posey deals with the subject of sight from all standpoints, and in writing avoids as far as possible technicalities. Four of the chapters are contributed by well-known eye authorities. The book is excellently illustrated and is likely to prove of service to medical practitioners.

NEOPLASTIC DISEASES. A Text-book on Tumors. By JAMES EWING, A.M., M.D., Sc.D., Professor of Pathology at Cornell University Medical College, New York City. With 479 illustrations. Cloth, $10. Philadelphia and London: W. B. Saunders Company, 1919.

THIS is an ambitious work in which the author has set himself the extremely formidable task of the differentiation of tumors regarded from the standpoint of their origin, structure, and natural history. It is somewhat astonishing that a good deal of ignorance exists with regard to the exact nature of the several members of the tumor family. Or rather, perhaps, it will be more correct to say, that the medical practitioner has looked upon tumors from a broad aspect and has considered fibromas, sarcomas, or cancers as, to all intents and purposes, the same and has treated them accordingly. Moreover, the causative agent of all malignant tumors has been deemed identical which, in the opinion of Dr. Ewing, has greatly retarded progress of knowledge and, what is more, has militated very considerably against successful treatment. This has established a state of confusion, almost of chaos, which the author has endeavored in this work to illuminate. While he does not claim that he has entirely succeeded in his effort to present tumors as specific diseases, he does claim that the effort is, at any rate, in the right direction. The work is distinctive and will undoubtedly serve as a guide to a further and more intimate knowledge of tumors, which, after all, means better methods of treatment. The book is artistically and profusely illustrated.

ABSTRACTS OF WAR SURGERY. An Abstract of the War Literature of General Surgery that has been published since the Declaration of War in 1914. Prepared by the Division of Surgery, Surgeon-General's Office. Price, $4.00. St. Louis: C. V. Mosby Company, 1918.

AS a result of the war, many new surgical measures have been introduced, and many old procedures have been modified. There has been published quite an extensive literature on the subject. But before we can appreciate at its proper value the result of these changes and innovations, it is necessary to have a summary of what has been done. The present volume supplies, to some extent, this need. The reader has, here, an abstract of over one hundred papers bearing on War Surgery. These are classified under the general headings of: General topics, Wound infection and treatment, Tetanus, Gas gangrene, Abdomen, Chest, Cardiovascular surgery, Joints, Fractures, Burns, Anesthesia in warfare, Trench foot, Foreign bodies, Peripheral nerve injuries, and Jaws and face. The whole volume is well worth reading; but we would draw special attention to the two articles at the beginning of the book: The development of British surgery at the front, and Development of British surgery in the hospitals on the lines of communication in France. Each of these papers give an interesting and authoritative account of what was done in the war, and of the aims of those in charge of the wounded. This is a useful volume, and should have an extensive sale.

A COMPEND OF PHARMACY. By F. E. STEWART, M.D., Ph.G., Phar.D., Charter Member of the American Therapeutic Society; Formerly Professor of Materia Medica, Medico-Chirurgical College, Lecturer and Demonstrator of Materia Medica and Pharmacy, Jefferson Medical College, Medico-Chirurgical College, and Woman's Medical College of Pennsylvania, Philadelphia; Quiz-Master in Chemistry and Theoretical Pharmacy, Philadelphia College of Pharmacy, and Chairman of the Section on Materia Medica and Pharmacy of the American Medical Association; Associate Editor of the Therapeutic Gazette; Editor-in-Chief of Merck's Archives, etc. Based upon Prof. Joseph P. Remington's "Text-Book of Pharmacy," the United States Pharmacopœia IX and the National Formulary IV. Ninth Edition. Revised and Enlarged by HEBER W. YOUNKEN, Ph.G., Ph.D., Professor of Botany and Pharmacognosy and Director of the Microscopical Laboratories in the Philadelphia College of Pharmacy; Professor of Biology, Ursinus College; Formerly Professor in Charge of Botany and Pharmacognosy and Quiz Master in Materia Medica, Medico-Chirurgical College. Price, $1.50. Philadelphia: P. Blakiston's Son and Co.

THIS little compend contains much information concerning the official products and preparations. In a condensed, yet clear, manner the reader will find in this volume much of the chemistry and materia medica of the Pharmacopœias and the numerous tables summarize the various preparations referred to in our two national authorities. Many physicians who might be deterred by its size and cost from consulting Remington's Pharmacy will find the present volume of more than ordinary value. In spite of its numerous chemical formulæ and equations, we have found very few misprints in the book.

A MANUAL OF GYNECOLOGY. By JOHN COOKE HIRST, M.D., Associate in Obstetrics, University of Pennsylvania; Obstetrician and Gynecologist to the Philadelphia General Hospital; Obstetrician to St. Agnes' Hospital; Gynecologist to Mt. Sinai Hospital; Gynecologist to the American Hospital for Diseases of the Stomach; Fellow of the College of Physicians, Philadelphia. With 175 illustrations. Price, $2.50. Philadelphia and London: W. B. Saunders Company, 1918.

THIS volume presents in concise form the subject of gynecology from the practical point of view. In several sections he has dealt with the matter from the standpoint of the obstetrician and the gynecologist. A feature of the book is the attention paid to the operation of dilatation and curettage of the uterus, which in the author's opinion is an important operation. The book is graphically illustrated which serves to make clear the text. It is a work that should be useful to the practitioner and student.

A MANUAL OF DISEASES OF THE NOSE, THROAT AND EAR. By E. B. GLEASON, M.D., L.L.D., Professor of Otology, Medico-Chirurgical College Graduate School University of Pennsylvania. Fourth Edition. Thoroughly Revised. Price, $3.00. Philadelphia and London: W. B. Saunders Company, 1918.

THIS Manual was written in the first instance to supply students and general practitioners with the essential facts of rhinology, laryngology and othology in as concise a form as possible. It has been so well received that it has run into four editions, which shows that it has fulfilled the purpose of the author and has been well appreciated. The present edition has been very carefully revised and brought up to date and affords an excellent, brief but comprehensive, text-book for nose and throat and ear specialists, medical practitioners and students. A feature of the book is a full formula at the end of the volume of the therapeutic treatment of various forms of nose, throat and ear affections.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 21, 1918.

THE PRESIDENT, Dr. WALTER B. JAMES, IN THE CHAIR.

Tuberculosis Among European Nations at War.—Dr. JAMES ALEXANDER MILLER, Associate Director of the Rockefeller Commission for the Prevention of Tuberculosis in France, delivered this address, in which he reviewed the results of the extensive study and practical work conducted by the commission in the year 1917-18. He stated that the problems of civilian disease and mortality had come to loom very large in their association with the resources of nations behind the armies in the field. Tuberculosis had always played a leading rôle among the preventable diseases, and from the campaign against it many of the fundamental principles of public health had been developed and applied widely to other diseases, particularly in this country. With these fundamental principles in mind and forming sources of information at the command of the members of the Commission, the task of instituting in France a vigorous modern public health program offered the possibility of striking results. In addition, the relation between cause and effect in such a program promised to be more susceptible to critical analysis than was possible in countries like America, where the campaign for better hygiene had been a more gradual development. Complete information of conditions obtaining in France and, though less complete, knowledge of the situation in Great Britain, Belgium, Germany, Austria-Hungary and Servia, had been secured. The influence of the war upon tuberculosis problems fell into two general categories, first in the armies, and secondly among the civilian populations. The situation as regarded tuberculosis in the French army had been very much exaggerated, and a careful estimate based on the official figures of examinations for tuberculosis showed that in reality the maximum amount of tuberculosis necessitating discharges from the army was 1.75 per cent. in the early months of the war, and .63 per cent. in the later months of the war after the large numbers of cases of active tuberculosis which had been mobilized had been eliminated to a great extent. The number of cases of tuberculosis developing in the French army during active service had been found to be no greater than that in a similar group of men taken from civilian life in America. The physicians and surgeons of the French Army had without exception declared that the physical condition of the soldiers was much better than among similar groups who had been mobilized into industry, or than it would have been in their normal civilian life. Many examples of early or latent tuberculosis becoming arrested after two or three years of military service had been brought to the attention of the speaker. Some interesting data had been secured regarding the experience of the British army, through the courtesy of the War Office and of the Medical Research Committee which was conducting an analysis of all the cases of sick and wounded in the British army; and it was known that up to Dec. 31, 1915, pulmonary tuberculosis had formed only 1.1 per cent. of the whole number. This equaled the figures obtainable in peace times, since for fifteen years pulmonary tuberculosis had been almost a constant factor in the British army, and it would therefore seem justifiable to conclude that the conditions of the present war had not tended to increase the percentage of tuberculosis in the British army. The information supplied concerning tuberculosis in the Belgian army before and after the war showed that Belgium, with an extremely low incidence of tuberculosis in its army before the war, nevertheless had had this rate distinctly lowered during the war. Turning to the American army, short and inconclusive though experience concerning it had been, nevertheless tuberculosis had proven to be in no sense a large problem, only a few cases of pulmonary tuberculosis having been returned to the United States from the army in France, and comparatively few cases had developed in France. The effect of gas warfare and of chest wounds upon the subsequent development of pulmonary tuberculosis had been watched with great interest and it had been definitely proven that contrary to expectations based upon currently accepted notions, pulmonary tuberculosis did not develop as a result of these severe mechanical irritations of the respiratory tract. From all the sources available to the Commission, it therefore seemed entirely justifiable to conclude that tuberculosis had not been increased because of the influence of the war upon the armies in the field, and that if anything the effect of army life was to diminish the hazard from pulmonary tuberculosis.

For any effect of the war toward the increase of tuberculosis it was necessary to look to the conditions among the civilian populations, and therefore studies were conducted along this line. In France the tuberculosis situation among the civilian population was truly a serious one in the cities, but in the rural sections the mortality statistics were comparatively low. The war could not be proven to have materially increased the tuberculosis death rate generally throughout the country, as was shown by the comparative mortalities before and during the war in the city of Paris. The conditions in France having their influence upon the tuberculosis problem were (1) the tremendous overcrowding in the larger cities due to the influx of refugees from the invaded districts, the unprecedented development of war industries in these centers, and the total lack of new housing construction since the beginning of the war; (2) the excessive industrial pressure which had drafted thousands, especially women, into unaccustomed industry and usually under the most unfavorable hygienic conditions of long hours, excessive strain, and special hazards of the working environment itself; (3) the prolonged physical and mental strain incident to the war, nowhere more noticeable than in France; and (4) excessive alcoholism in such cities as Paris and Marseilles and certain country districts as Brittany and Normandy. It was both interesting and important to note that there had been no real problem of undernourishment in France. Food in general had been sufficient and available to the working classes. During the latter part of the investigation, however, reports had come in of more general malnutrition seen among dispensary patients. This condition would lead to serious results if continued.

In England the antituberculosis campaign had been well organized and along similar lines to those in America. It had, of course, been disturbed by the war, but the system of state organization with special tuberculosis health officers for each county, had in general held it in line most admirably, handicapped but not interrupted. The public health records were also kept in most excellent form. Reports for the year 1917-18 showed a distinct increase in pulmonary tuberculosis in 1915, 1916, and 1917, but other forms had not increased. This increase was more marked among women. This excessive mortality among women was attributed to their extensive employment in munition and other industrial occupations under conditions of exceptional stress and strain, often associated with crowded lodging accommodation. The most striking increase was among women of the age group 15-25, and it was most evident in the industrial centers. Certain occupations among city dwellers showed results only explicable by the assumption that such employment introduced a special factor which favored the development of tuberculosis. In general it might be said that poverty among the working classes of England did not appear a striking war condition on account of high wages and plenty of work, and that also here, as in France, the food factor was not important. Food in England was most carefully distributed by an efficient rationing system, but the supply was sufficient so that malnutrition had not increased even among the poorer classes. Their experience in France, therefore, was strikingly corroborated by that of England, so that the effect of the war among civilians appeared to be a problem of industry in the larger cities, especially among young women, with overcrowding an important although possibly a secondary factor, and with no influence attributable to insufficient food.

In regard to conditions in occupied Belgium, a very full and remarkable report as to the health conditions therein had been made by the Inspecteur de Service de Santé, M. Hulot. From all the numerous sources which went to make this report, the testimony was

unanimous in stressing infant mortality and tuberculosis as the urgent problems. There was a startling increase in the comparative mortalities of Brussels, Antwerp, and Liege, especially in 1917, the increase of 1917 over 1912 being 91 per cent. in Brussels, 94 per cent. in Antwerp, and 102 per cent. in Liege. The report did not indicate any unusual distribution of this alarmingly increased mortality among the different age and sex groups, although the great increase of tuberculosis among children was indicated. The story of food conditions was the same from all parts of Belgium. The food ration accorded to them for the households, counting only adults and young people, was altogether insufficient from the point of view both of quantity and of quality. The average adult daily ration for all of occupied Belgium had averaged between 1,800 and 2,000 calories for a period of over a year. The correlation of the increase of tuberculosis with the insufficiency of food in Belgium afforded a striking contrast with the conditions noted in France and England. Belgium, in spite of the appalling condition of affairs within her borders and staggering under her frightful ordeal of four and a half years' duration, had drawn up a program to combat tuberculosis that was modern, complete, and admirable in every detail and which was worked out before peace was declared and held ready for immediate operation as soon as the country was evacuated by the Germans. And what was most astonishing, the Ligue Nationale, struggling under its heavy burden of supplying relief of all sorts, had in addition raised a fund of 6,000,000 francs for tuberculosis with which this program was to be launched.

Accurate information from Germany was, of course, scanty, but the official publications of the Imperial Health Office, showing births and mortality among 27,000,000 people, or about one-third the total population of Germany, gave comparative deaths from tuberculosis in 1913 of 40,625, in 1916 of 48,446, and in 1917 of 67,208. The percentage of tuberculosis deaths and total deaths were 11.2, 13.3, and 12.7 respectively for these three years. There was a rise in the tuberculosis death rate from 1.51 per 1,000 in 1913 to 2.31 in 1917. The general death rate had risen from 12.2 to 17.9. The big increase in both did not occur until 1917, and another point of interest was the tremendous fall in the birth rate, 1917 being about half of that of 1913. A circumstance difficult to understand was that the infant mortality rate in 1917 was not very marked and that of 1916 was below that of 1913.

The only available data upon conditions in Austria-Hungary included figures for Vienna, Prague, Triest and Budapest. In the period shown, which was only from thirty to thirty-five weeks, the deaths from tuberculosis increased from 7,311 in 1913 to 11,755 in 1917, or over 60 per cent. Conditions were far worse in Austria-Hungary than in Germany. The probability was that bad food conditions were primarily responsible.

Little was known of conditions in Serbia, but such indications as were available showed 15 per cent. of the population to be suffering from tuberculosis. Thirteen per cent. of the Serbian refugees in France were suffering from tuberculosis. The remnant of the Serbian nation in exile showed an enormous incidence of tuberculosis as indicated by the figures given for those in France. The situation was probably of equal seriousness in Russia, Poland, Roumania, and Armenia, to say nothing of the enemy nations themselves, and there could be little doubt that tuberculosis would be one of the most frequent consequences of the terrible suffering and disease which war had brought to hundreds of thousands of the civilian population.

There were seven lessons to be learned from this brief review of the tuberculosis situation in Europe as occasioned by the war: (1) The experience of the armies indicated that there was less hazard than supposed in hard physical exertion and exposure, as regarded the breakdown of resistance to tuberculosis, provided these conditions were combined with open-air life. (2) There was relatively infrequent development of pulmonary tuberculosis as the result of the exposure to poisonous or irritating gases and of chest wounds. (3) Following the system developed in the American army of rapid but systematic chest examinations in the elimination of tuberculosis suspects, large groups, especially industrial workers, could be detected early. (4) Food is a very important factor in increasing mortality from tuberculosis, and the effects of long-sustained malnutrition are cumulative. (5) The tuberculosis situation in France and England, and its analysis as an industrial condition among young women, would indicate the importance of the place in economics of industrial hygiene. Systematic supervision of working conditions should go hand in hand with home supervision and sanitation of workers. (6) Two phases of the experience of the Tuberculosis Commission in France possessed value for adaptation to the general tuberculosis problem; they were the organization of the educational propaganda and the training of health visitors for tuberculosis and child hygiene. Regarding the former, the combination of American ideas and French art had produced effects that deserved imitation. The training of health visitors had proved a great success in France, proving that it was unnecessary to employ only graduate nurses in this work. There was need for a very much larger number of such workers, a one-year course fitting them for very effective medical social service. They were in no sense nurses, but rather inspectors and supervisors of home and living conditions, teachers of hygiene, and agents for social reform or care. They should have training for these special duties, which would require at the longest two years. The functions of visiting nurse and health visitor being distinct, their training should become so also. (7) The last suggestion to be presented from this war experience was that of reeducation and vocational training for the tuberculous. The industrial colonies developed in France and England presented possibilities not only for the disabled soldiers but for the tuberculous civilian as well. The after care of the discharged sanatorium cases was as yet an unsolved problem, which was largely due to economic conditions, the patient being under the necessity of supporting himself and perhaps a family as well as soon as possible, and reeducation of the tuberculous would be a long step in the direction of a solution. A beginning had already been made in this direction, and the movement should enlist the support of all interested in antituberculosis work.

Dr. David R. Lyman, president of the National Association for the Prevention of Tuberculosis, related the circumstances under which he went to France to assume charge of the antituberculosis work which Dr. Miller had established and which he said he had found more fascinating than any work of the kind with which he had ever come into contact. In the district where he was stationed Dr. Miller had had to combat a strongly entrenched phthisiophobia, yet he had succeeded, by a wise selection and combination of the best features of antituberculosis work from many sources, in building up a very complete program for handling the tuberculosis problem in France. As a result he had the French people in love with the Americans and with their methods of combating tuberculosis. By telling the French people that the plans they were putting into operation were the ones followed in America they had been enabled to put into effect a very complete program and to do what they felt should be done with no one to say "no" to them. If the public health workers of America could see what was regarded as the American plan they would be greatly surprised, for the plan included a comprehensive program for giving complete relief to the families of tuberculous individuals. When a case of tuberculosis was reported the Tuberculosis Commission sent a trained social worker to look after the economic condition of the family. If the person affected was the breadwinner and he had been compelled to stop work, his wages went on; every member of the family was given a physical examination, and it was seen that the family, and particularly the children, had sufficient food of the proper kind to build them up, and that all other necessities were supplied. In this way the children were put in good condition and could acquire an immunity to the disease. When a victim of tuberculosis was found in a house that was in bad sanitary condition and the Commission was asked what they were going to do about it, they replied that in America they would rent another house for the family and if one could not be rented they would build one. In this way it was brought about that when such a case was reported the mayor sent the village archi-

tect to see what could be done to remedy the situation. If possible the house was put in sanitary condition, and if this could not be done better quarters were found for the family. The Tuberculosis Commission had been the means of saving the lives of many refugees who had come to France, and while they had saved the lives of many children, there were also many who would always have impaired physiques as a result of their suffering and privation. In order to alleviate the results of the hardships these people had suffered, in so far as possible, this work must be carried on until the world was back on its feet again. Dr. Lyman said he believed the American Red Cross had done more than anything else to win the war until our boys actually got into the trenches. He related specific instances showing how the relief work had served to hearten the men in the trenches by making them feel that their families were well cared for. If the Red Cross was to keep on with this work we would have to continue to dig down into our pockets as deeply as we possibly could until the job was completed, for what remained to be done was fully as important as what had already been done. Dr. Miller had visualized what the war would do in awakening and shaking us up and making us take stock in all lines of endeavor and especially in public health work, and had called attention to the necessity of adjusting ourselves to a new viewpoint. Dr. Lyman said he hoped that we would come out of the war with all our doctors in touch with the tuberculosis problem, and knowing what was active tuberculosis and what was not, as their experience in the camps had taught them a great deal in this respect. He hoped we would have tuberculosis back as one of the problems of public health and one belonging to the general practitioner instead of a specialty of medicine of which one half the medical profession and all the general public were scared to death. In France when a man or woman came to them and they diagnosed the condition as tuberculosis, they had told them that in America under similar circumstances the children would be cared for and the parent who was suffering from tuberculosis put in a general hospital, and then the French people permitted such a plan to be carried out; he hoped to see the day when this could truthfully be said of America. He desired to bring a realization of the fact that tuberculosis could not be considered a distinct and separate disease in the handling of which all one had to do was to find the infecting micro-organism and then lay down rules as to its management: this could not be done since the tuberculosis problem was woven into everything that came into our lives, working conditions, housing conditions, occupation, amusements, everything. It was a big problem of general medicine and it was to be hoped that the general practitioner would get it back. The experience with tuberculosis in the army had staggered them all. He, however, had a little hesitancy in ascribing the good results that had been observed to open air alone. In explaining these results one must not forget that other factors had entered in and contributed to the results that they had observed. The men were under control and regular discipline, and they had plenty of good food. Having had, as a boy, experience on a farm, he had never thought much of the so-called light farm work that was recommended for the tuberculosis patient, but his experience in the camps had taught him that these men with incipient tuberculosis could do out-of-door work if their lives were regulated and they had good food at regular hours and did not kill themselves during play hours. Food and late hours are important factors in relation to the tuberculosis problem among civilians. A man naturally thought that it was his work that was killing him, because that was the part of his life that as a rule he did not like. The truth of the matter often was that the man kept late hours, slept a few hours, then got up and rushed off to work not properly fed. The basis of alcoholism was that the average woman knew nothing about food values or cooking. More men were driven to the bar-room to help forget what their stomachs were trying to digest than for any other cause. This matter of food and cooking was a great vital question. In our system of education we should see that our girls knew how to buy, care for, and cook proper food for the family on a basis of scientific training instead of trying to pick it up in a haphazard way after they were married. No other question was as important as proper food and proper nutrition. As to the trained nurses and trained house visitors, he thought we should let down the bars so far as public health work was concerned, as nine out of ten women were born nurses anyway. He had had experience with a great many women who had had little or no training who had done excellent work in this field. In closing, Dr. Lyman emphasized the fact that there was a great expansion of public health work ahead and that we should learn our lesson from the experiences abroad. If we did not get the most out of this experience that we possibly could we were not fit to be called Americans.

Dr. WICKLIFFE ROSE, General Director of the International Health Board, called attention to two or three points in Dr. Miller's paper as worthy of special emphasis. The most important of these was that suggested by the charts exhibiting the relation of death rate to birth rate in the several warring countries. The most serious problem which these nations would have to face during the period of rebuilding was the necessity of restoring their lost man power. Houses might be built, destroyed farms reclaimed, industry and commerce reestablished, and the nation's prosperity restored—provided the nation had the men. All depended upon productive man power. The charts showed that in Belgium, France, Germany, Austria, Serbia and Poland, the death rate for the last three or four years had been far in excess of the birth rate. And conditions would seem to indicate that in some of these countries at least the birth rate would continue relatively low for many years after peace was restored. To this fact of declining population must be added the further significant fact that war had taken its toll of men in their prime. These nations had lost in killed and permanently disabled a large percentage of their producers, their leaders in industry and commerce, in science and art, and the whole field of thought and action. Of that portion of the population not engaged at the front, particularly in the invaded regions, war had borne most heavily on the children. In Belgium, northern France, Poland, Serbia, and in Austria-Hungary, the death rate among children, due to lack of food and of proper care, had been high. In the work of rebuilding which these nations were facing, foremost place therefore must be given to the conservation of life and health and working efficiency. And for at least a generation the conservation of children must be given first consideration. Dr. Miller's paper had made it clear that in undertaking to restore their lost man power these nations would have to reckon with tuberculosis—a serious menace in times of peace, made vastly more serious by the conditions of war. And tuberculosis also took its heaviest toll of children during the first two years of life and of men and women in their prime. The fight on tuberculosis to be successful would involve the essentials of a general public health program. Some diseases, as malaria or yellow fever, might be controlled by specific measures without raising the question of personal hygiene and with but slight effect on general public sanitation. The prevention of tuberculosis was not so simple. The disease was too organic, had woven itself too intimately into the fiber of social and economic life to be controlled by any specific procedure. A study of tuberculosis in this country and of our fight against it (undertaken some months ago and still in progress) seemed to indicate that our tuberculosis rate had varied not with the special measures which have been directed against it, but rather with more general social and economic conditions and with progress in personal hygiene and public sanitation. It was of great significance, therefore, that most of the countries engaged in the war were now projecting national programs of public health. In our own country, Congress had greatly increased its appropriations for public health purposes and the Treasury Department had under consideration a reorganization in the interest of greater efficiency of our Federal health service. For months England had been formulating a plan for the unification of all health activities under a ministry of health. In France, where nothing approximating an efficient health service had existed hitherto, opinion was forming in support of a national health program as one of the

foremost measures of reconstruction. In both France and England the importance of adequate institutes for the cultivation of hygiene as a science and the training of workers for the public health service was receiving intelligent consideration. Belgium even under the severe strain of German occupation, had raised a considerable fund with which to begin a fight on tuberculosis as soon as peace brought freedom, and proposed to back this with measures of general sanitation.

Austria had begun a reorganization of her national health service just before disintegration set in, and a letter just received from Serbia stated that the organization of a national health service with child hygiene and the prevention of tuberculosis as a part of its program was now under consideration by the Serbian Government. This focusing of attention as never before on the importance of conserving life and health was one of the best fruits of this life-destroying war. And we might derive the greatest satisfaction from the thought that after four years of bitter conflict these same nations might find in a program of health a common meeting ground where the gain of each would be a contribution to all.

Dr. HERMANN M. BIGGS said he merely wished to express his appreciation of Dr. Miller's remarkably interesting and inspiring paper and to voice his gratification that this country was represented abroad by the men who did represent it, Dr. Farrand, Dr. Miller, Dr. Lyman and their assistants, the best products of the tuberculosis campaigns that had been going on here for the last thirty years. There was just a word to be said of the International Health Board. The work of the Rockefeller Foundation in establishing the International Health Board was the best example of broadminded, far-seeing philanthropy which he had ever seen. This work was an example all over the world in extending public health programs and demonstrating methods of control of infectious disease and in teaching people to help themselves in evolving their own health programs. It seemed to him that the work of the International Health Board was the greatest achievement of the time. The excess of death rates over birth rates to which Dr. Miller had called attention was the most portentous problem that confronted France and it was further enhanced when we recognized the fact that the population of France had been almost stationary for a century. Dr. Biggs quoted statistics in confirmation of this statement and also showed that the death rate had declined but little for a number of years and was above that of this country and of Great Britain and indeed of most other foreign countries. He felt great apprehension for the future of France unless the whole economic life of the people could be altered and the birth rate quickly increased; if that could not be accomplished the future of France was certainly dark.

Stated Meeting, Held January 16, 1919.

THE PRESIDENT, DR. GEORGE D. STEWART, IN THE CHAIR.

THIS meeting was held in cooperation with the Orthopedic Section.

Remarks on the Value of: (a) The Moving Picture in Teaching Surgery; (b) The Moving Picture with Time and Distance Records; (c) The Animated Diagram; (d) Femoral Hernia Operation.—Colonel WILLIAM O. OWEN, M.C., U. S. Army, made this presentation, in which he first described three varieties of moving pictures, each of which had its own advantages when taken at the normal rate of sixteen to one second and a fourth by a slow or rapid take. Up to the present only one of these methods had been used to any very great extent, that was the sixteen to one, or the old style, the common method in which the operator was taken with his patient and with his assistants, but oftentimes the blood blocked out the field so as practically to obliterate the very things it was desired most to see. Another method, much less well known, was that which had been taught the writer by a friend, Frank Gilbreth of Providence, R. I., which consisted in taking the picture of the scene you wanted upon a background and floor of four-inch squares (one decimeter approximately), so that the four squares appeared in every portion of the field at all times. In the field at the same time was placed a clock in which there was no escapement, since the fractions of time involved were very small and the escapement introduced a dead point which might possibly interfere with the accuracy of the work. This method would be of particular value in the medical world when it had been developed as it had been in the engineering world, for the examination of spasmodic seizures, of limps of various characters, of the reflexes, etc. One might imagine the patellar reflex explained by stop-motion when teaching the student his physiology and this followed by a moving picture of the reflex in the living individual. By using the device known as a simultaneous motion chart, taking the pictures from sixteen to sixty or eighty per second, as the necessities of the work required, and then throwing these pictures on a screen and charting in vertical sections the time element of the cycle of movement; and on the horizontal the distance moved in each fraction of time by each individual portion of the body involved in the cycle of movement which it was desired to study, and as either the time element or the distance traveled in the cycle changed, the quadrangle of each cycle of the individual part changed its shape, being lengthened or shortened in one or the other direction, so when one had charted two or three cycles of the movement, the irregularity became instantly visible upon the simultaneous motion chart even though they were not seen on the screen in the picture. By means of a simultaneous motion chart it was possible to make direct and positive diagnosis of limps, spasmodic seizures of hysteria, and reflexes, by means of the regularities and irregularities shown. There was yet a third kind of moving picture that was, perhaps, as a teaching method, of far greater importance than either of the other two, or perhaps than the two combined. This was what the speaker had chosen to call the "animated diagram"; it was what was constantly seen in the moving pictures in the so-called Mutt and Jeff picture. As an illustration of this kind of picture Colonel Owens cited the femoral hernia operation by the inguinal route. One watched the artist's hand appear drawing in the torso of a woman; then the bony pelvis appeared; then Poupart's ligament; then Gimbernat's ligament. One could see the aorta subdivide, the internal and external iliacs drop into place, and the femoral artery go through under Poupart's ligament to its own place. It was, to say the least, interesting to see the knife march into place, make the proper incision, march out; the retractor come in and open up the tissue, and layer by layer the operation proceeded with the moving diagram ever changing and making a perfectly clear outline of every detail of the operative procedure one might wish to explain. One of the speaker's ambitions, he stated, was to make a moving picture show in detail the nerve impulses and the effects which followed in the heart, and the irregularities of action resulting therefrom, indicating the difficulties in the ventricles when there was an interference with the function of the bundle of His, etc. He had also had the ambition to make a transparent image of the child in growth, to make the organs grow under the eye, in their definite relationship one to the other. It would be very interesting to see the stomach and intestines grow and increase in length, and to see the forming of the peritoneum in place, to see the stomach and duodenum turn, fall back, and form the lesser curvature, and to see the blood-vessels grow down into and with the mesentery, etc. One of his friends desired very much to make an animated diagram showing the cell changes in the growth and repair of bone. He had begun the work, his diagrams were in the hands of the artist, but the war ended and both the artist and the doctor were anxious to return to civil life, and another dream was gone. The speaker pictured that as a method of teaching he put on the screen an animated diagram of just what his idea was of the operative procedure he wished his students to know, and he then performed the operation as nearly as he could like the animated diagram, and had the picture taken. He would then have the student read over the description of the operation, see the

animated diagram, see the motion picture of the actual operations, and then when he saw the operation at a clinic he would carry with him a very much clearer picture of what the instruction was than he could possibly receive in any other way with many times the amount of study. One's own ability to think in diagram was his only limit by this method and with a camera one could make the negative in his own hours. Making this negative was quite easily accomplished by remembering the principles upon which these animated diagrams were put into movement. When the eye received an impression it lasted only a fraction of a second, less than one-eighth, and then another impression of the same object within one-quarter or one-half inch of the same position, and the series of these were impressed upon the retina. The result was that the eye saw a continuous movement. For instance, one of the pictures shown was that of a chisel being driven into a bone by a mallet. To produce this, pictures of the chisel and the mallet were drawn upon a piece of cardboard. These were then cut out in the black lines of the drawing. The next step was the drawing of the foot and the bone to be cut. The drawing of the chisel cut out of paper was laid upon the drawing of the foot and the picture was taken. The picture of the chisel was then moved a short distance, another picture taken, and a series of these pictures taken with a picture of the chisel gradually approaching and assuming its position to cut the bone. Then when this was done the mallet picture came in by the same process, and when it got into the position from which the blow was to be struck a picture was taken; then the next picture represented the mallet in the position to strike, then it was placed on top of the chisel, and since two blows were to be struck the next picture was taken by putting the picture of the mallet back into place from which the original blow was struck. The writer described the teaching of physiology with an animated diagram of the blow on the tendon, the impulse flowing up the nerves of the thigh to the centers, and the reflexes back down the nerve to the muscle with the muscular contraction. One could then show an individual giving this reaction in a moving picture; then the student would not forget it when it was shown to him at the clinic. Heart studies with the animated diagram and reflexes studied in the same way would certainly reward the student and enable the teacher to explain in a far more satisfactory way to beginners than otherwise would be possible. Colonel Owen suggested that a very valuable study would be to show the cripple at work, particularly those men who had trained themselves so that they could carry their own weight. He knew of a one-armed bricklayer who earned more in laying brick than the two-handed did in the majority of cases. It would be of very great value to get a rapid motion picture of this man with time and distance; then his automatic motions would be registered. The simultaneous motion chart would solve his motions and they could be analyzed slowly and deliberately and other one-armed bricklayers taught his method, and thus his automatism would become theirs.

Abstracts from Lectures on: Deviation from the Natural Function of the Foot—Exercises for Flat Foot—Fallacies of So-called Arch Supports. Tendon Transplantation for Flat Foot: (a) Animated Diagram: Taylor's Technique; (b) Moving Picture of Taylor's Operation; (c) Moving Picture of Leo Mayer's Operation.—MAJOR R. TUNSTALL TAYLOR made this presentation. He stated that as supervising surgeon it soon became apparent to him in lecturing at various cantonments or to any large body of students that simply the verbal lecture, with the limitations of the human voice and absence of illustrations or clinical material was inadequate for attention and retention by the memory; charts and slides were impractical, so that the moving picture on his initiative and with the hearty cooperation of Colonel Owen, was established in the Surgeon General's office and the other specialties soon availed of it. In creating these lectures he had in mind not only military instruction, but adding teaching facilities available for use in our civil medical schools, upon request to the Surgeon General. It soon became apparent to Colonel Brackett, Director of their Division, and the rest engaged in this instruction that it was expedient to go into the most rudimentary facts regarding locomotion, the prevention of avoidable disability, and the recognized treatment of the more common affections of the lower extremities. The writer has prepared some thousands of feet of film on this subject alone and the exhibition of the evening gave only disjointed snatches of them here and there. Their efforts were to portray in detail the technique of surgical reconstruction in tendon, muscle, bone work, etc. He would also show a portion of their work on posture, even now incomplete, as they looked to New York as the home and Dr. Henry Ling Taylor as the father of the American Posture League here. The moving picture film would bring the student into closer touch with clinical material, certain symptoms, such as neuroses, epileptic seizures, tics, etc., than were oftimes available in hospital routine instruction and difficult to describe, but the so-called close-ups as shown by the movies would bring the student intimately in contact with the operating table, which was often not possible from an amphitheater seat. The details of arterial nerve or intestinal anastomosis, bone grafting, application of mechanical principles of direction and technique in tendon and muscle transplantation for deformities and application of deep sutures were brought home and fixed in the memory as by no other means of instruction, save actual experience later in the procedures themselves. This mode of instruction in conjunction with didactic lectures had been found to yield a higher average mark per student than any other mode of teaching. The moving picture possessed the advantage over the lantern slide in that the component parts of a lecture could not be disarranged, broken, or lost, nevertheless inserts or additions could be made, almost unlimited positives could be printed from the original negative at the same cost as slides, and films were lighter and more easily transported than slides. A simple modern attachment was now available for stopping the moving picture machine at any point, without burning the film, where it was desired to emphasize some special feature. By means of the moving picture in comparative teaching of the future, the medical student would also be able to see the modifications of several surgeons in performing a given procedure; thus a class might see the technique employed at the clinics of this and other countries at the same sitting and appreciate the value of the points made in each. It was thus very broadening in its educational possibilities. Or a clinical professor who wished to illustrate his systematic course of lectures, but was lacking in clinical material, could resort to a moving picture record of the desired cases, symptoms, signs, operation, etc.

The films of the Army Medical Museum would be available to teachers in the army and medical schools and the profession, just as the books in the Surgeon General's library were for study or reference, provided transportation, safe handling, and return in good order or replacement were guaranteed. Those who wished to own prints could purchase at five cents a foot. It was hoped that the profession would cooperate in giving films to this department or allow it to make copies of existing negatives. It had been brought to the attention of the Surgeon General's office that certain commercial film companies, having made medical films, wished to charge this department for copies or the profession for exhibition purposes on a commercial basis. Physicians could easily and should specify, when approached to demonstrate a new procedure for a "movie" company, that a copy be sent the Surgeon General for the profession at large before permitting it to be made.

Many facts in the prevention of acute foot strain, the so-called flat foot, and the explanation of a large number of torn ligaments at the knee and ankle in trench jumping at the cantonments had been explained by this department, and moving pictures prepared showing how to jump correctly and prevent such disabilities. Also as a result of this film, instruction in standard foot examinations, shoe fitting, correct balance and marching, to be used in the Army, had been or would shortly be issued by the General Staff as general orders. By diagrammatic or "stop-motion" line-drawing or "animated drawings" as they were called, a most valuable instructive preliminary was at hand to precede a picture of an actual operative procedure. Demonstration of details in brace construction, fitting, and therapy, and

especially in recording, charting, and measuring departures from normal gait was an additional aid to orthopedic surgery, divested of the costly obstacle which had heretofore prevented its addition as a routine in the teaching of standard methods by many. The writer's plan in teaching students any given operative procedure was to show them the "animated drawing" first, then a "close-up" of an actual operation, another surgeon's technique in that condition, and, finally the operation itself, on the living subject, with illustrative cases before and after the operation. It was felt that with this method the knowledge would stick. Orthopedic men were under great indebtedness to Colonel Owen for having all these films made, which were of such direct and practical value in their work.

After this introduction Major Taylor gave a motion picture exhibition on the topics mentioned in his subject.

WESTERN SURGICAL ASSOCIATION.

Twenty-eighth Annual Meeting, Held in Chicago December 20 and 21, 1918.

THE PRESIDENT, DR. JAMES F. PERCY OF GALESBURG, ILLINOIS, IN THE CHAIR.

Our Duty to the Industrial Army.—Dr. R. W. CORWIN of Pueblo, Col., said our duty as surgeons to the industrial army might be considered under two heads: (1) Treatment after injury, and (2) treament before injury—surgical prophylaxis. In the army much stress had been placed upon keeping men fit and their power of resistance high. Very largely prophylactic treatment had been left to the welfare and to the medical department. The war had emphasized that physical resistance was of vital importance, especially in patients suffering from shock and wounds, and that a person in the best physical condition was in the best condition to endure operations. While in Belgium and France he saw soldiers, seriously wounded, brought to the hospital and they underwent extensive operations, and cases of profound shock rapidly recovered and returned to the front for active duty. We were told that of the wounded reaching casualty stations 95 per cent. recovered and 70 to 80 per cent. returned to the firing line within forty days. The war had further demonstrated that regular physical exercise, proper amount of sleep, rest and recreation, good food and minimum dissipation, were far superior to the go-as-you-please habits of the industrial army. What were some of the prophylactic duties of the surgeon? In a broad sense to educate the employee, obtain the endorsement of the employer, urge national and State cooperation, make known the laws of eugenics, and insist that the breeding of man is as important as the breeding of cattle. Specifically we should teach first aid, surgical hygiene, and sanitation. We should teach the nature of wounds, the process of wound healing, the process of wound poisoning, the importance of early attention, and the relation of health to wounds, the importance of not bandaging tightly, and the importance of the care of the feet. We should teach the importance of properly fitted shoes and the importance of position in lifting so as to prevent sacroiliac injuries. The industrial army demanded surgical protection as well as surgical treatment. Were we not to protect as well as save? Was not the surgeon best qualified to satisfy this demand? Had not the surgeon been too modest and permitted others to occupy his territory? Was it not time for the surgeon to assert his rights? Was not his duty to the industrial army plain? Now that peace was here, we should become instructors, not for war but for work.

Dr. JAMES F. PERCY of Galesburg, Ill., said that he never understood until the last few months why the soldier had so little respect for the civilian, but if you put a civilian in the army and train him he had not much respect for his civilian brother. To obtain the things outlined in this paper many conditions would have to be considered.

Dr. D. S. FAIRCHILD, Sr., of Clinton, Iowa, stated that he had examined some 16,000 men for army service and some 5,000 for railway service, and his conclusions were that we needed to inquire first into the ways of living. If every industry could establish a plan of examining the men received into service and then ascertain how these men lived, we would have something to go on in judging how to improve conditions. It was found in his State that 20 per cent. of the men rejected because of physical disability were under thirty, and over that age more than 30 per cent. were rejected, or about the same as the men for railroad service. It was thought that on account of war conditions it might be necessary for our railroad people to employ men who would not be accepted under ordinary conditions, and he took the opportunity of visiting the homes where many of these men lived—the older men who would not be taken under ordinary conditions—and he found the homes filthy and vice prevailed to a large extent. If we could start out with a plan of physical examination and follow this up by finding out how these people live, we would know what we must do in order to improve conditions.

Dr. JOHN P. LORD of Omaha said that we all realized the great amount of physical disability that had prevented men from being accepted in the military service, and these men were very anxious to have that physical disability removed in order that they might enter the service. The physical requirements were made in the various branches of the military service, and this had intensified the interest of people in their own physical conditions and they had tried to remedy them. Nurses ambitious to enter the nursing service would seek to have foot defects relieved so that they could get into service. If large corporations exacted these things, and many of them did, just as soon as these requirements were exacted the individuals were going to see to it that they were made fit for their jobs.

Dr. GEORGE N. KREIDER of Springfield, Ill., said he had examined 800 medical men and had been very much surprised to find a large proportion of medical men who were handicapped and were unable to get into the present war on account of overweight. At least twenty of these men had appeared before him and he refused to let them go in. They were very anxious to get in, and when he told them that it was possible for them to lose that weight and fit themselves for the service in a great number of cases—70 per cent. at least—they undertook to do it. In regard to shoes, he would say that cases of gastroptosis, heart trouble, and many other conditions were caused by bad shoes, and it was important for a surgeon to have this in mind and lend his assistance to any effort to get better shoes.

An Ambulatory Chair.—Dr. FRANK NIFONG of Columbia, Mo., said that the ambulatory chair which he showed inspired confidence in the convalescent and cripple and quickly gave self-reliance, which was such a necessary factor in promoting recovery. The patient soon went alone, without attendants, and much more quickly than if he depended on them. He realized that he was supported by a broad base and had no fear that he might fall. He sat down as soon as he was tired. He entered the chair from his bed with ease and might be encouraged to take care of himself from the beginning of his efforts, which was so important psychologically. The patient needed much less assistance from attendants and very soon might do without them. There was no danger from disastrous falls, from pressure paralysis and consequent wrist drop so often seen when weak and emaciated patients had tried to use crutches. It was well known how much delay in recovery was experienced when such an accident supervened.

The Surgical Treatment of Exophthalmic and Thyrotoxic Goiter, with Special Reference to Bilateral Resection.—Dr. NEIL JOHN MACLEAN of Winnipeg, Manitoba, said that the advantages of bilateral resection over unilateral lobectomy with partial lobectomy of the opposite lobe were (1) Minimum of injury to the parathyroids. (2) Absolute safety for the recurrent laryngeal nerve. (3) If for any reason further removal of the gland should be indicated, such as for recrudescence of symptoms of thyrotoxic activity or the rare but possible occurrence of malignancy, the one side could now be completely removed with an assurance that some portion of the gland remained. (4) It was a physiological fact that where there were paired organs, should one be removed the other underwent hypertrophy. This, while desirable in normal conditions, was what

we wished to avoid in the case under discussion, and this end was best obtained by double resection. (5) For cosmetic purposes, in the operation of lobectomy there was a well marked depression on the side from which the lobe had been removed, and on the other side the portion of the gland left produced an undue prominence, while in bilateral resection the neck was obviously symmetrical.

Purgation Before and After Abdominal Section.—Dr. HENRY T. BYFORD of Chicago condemned routine purgation before and after operations, because of the differences in the conditions of the patient and in the character of the operation. In abdominal surgery it was often required, but should be prescribed according to the condition of the patient and not by a routine method. The reason why it often did more harm than good was because the right dose of the right laxative was not given at the right time and under the right conditions. With regard to the question of purgation after abdominal section he divided the cases into four classes: (1) Those cases required early purgation in which a large incision in the middle or lower zone of the abdomen in connection with considerable displacement of intestinal coils, and sufficient intraperitoneal traumatism to cause subsequent adhesions to form. Under such conditions adhesions of displaced or kinked intestinal loops were liable to form and interfere with through and through peristaltic action, and resulted in obstruction and death. Early purgation helped to maintain a permeable canal until the adhesions had formed and the danger of obstruction had passed. (2) Cases in which there had been resection or extensive repair of the intestines usually required dieting and delay in purgation until a certain amount of protective exudate had had time to seal up the intestinal suture lines. (3) Cases in which sutured or denuded areas had been left were not so liable to the formation of extensive or permanent adhesions if peristaltic action was kept fairly active from the time of the operation. Early purgation might not be necessary, yet might be desirable. An accumulation of gas might require it in one case, while in another dieting or washing out of the stomach or a postural treatment might suffice. (4) Cases in which the incision had been small, with but little exposure or manipulation of the intestines, and in which all ligatures or denuded surfaces had been covered, would require purgation or abstemption from purgation for conditions that might happen to present themselves, without reference to the fact that the abdomen had been opened. When such patients had not been dieted, either before or after the operation, they might have early spontaneous bowel movements without laxatives or might merely require enemas to assist nature, while others who were accustomed to depend upon laxatives might require early purgation for relief. Patients who had been dieted before the operation and in whom the anesthetic had disturbed the stomach would have but little substance to the alimentary canal and might do better without a bowel movement for two or three days.

Dr. HOWARD HILL of Kansas City, Mo., said that no cathartic was necessary immediately before operation. Many people were found who were chronically constipated and they should receive the proper treatment, but not just before operation. Generally speaking, he felt that a person whose bowels had been moving normally up to the time of operation did not need a cathartic at that time.

Dr. C. H. WALLACE of St. Joseph, Mo., said that he had not been giving cathartics before operation for several years as his experience taught him that it was rather harmful. If a patient came with a history of regular bowel movements every day, never constipated, he got no purgative but an enema the next morning, and he believed that these patients suffered much less from postoperative vomiting than when purgatives were given beforehand.

Dr. A. J. OCHSNER of Chicago said that he had made a practical study of the use of purgatives before operation for the last thirty-two years. He had tried all of them, from calomel to castor oil, and had come to the conclusion that the principle laid down by the essayist was the correct one. If one gave cathartics, one must not give anything that would fill up the intestine again before the operation.

Dr. JAMES F. PERCY of Galesburg, Ill., stated that there was one thing that had not been mentioned, and that was the practice that some men had of giving an enema about four o'clock in the morning, so that the lower bowel was cleaned out at that time. It was not a very agreeable experience.

Fibrosarcoma of the Skull.—Dr. EARLE R. HARE of Minneapolis reported the case of a man, Mr. C. E., aged forty-six, Swedish, farmer by occupation, who presented himself, and in his case a diagnosis of fibrosarcoma or endothelioma was made. He had been advised against operation and *x*-ray therapy suggested. After careful consideration of all data obtained, operation was advised, accepted, and the tumor was removed, under novocain anesthesia. The tumor was largely limited below by the bones of the skull, but it had eroded through at two areas and passed downward between the cerebral hemispheres. It was necessary to resect an area of the dura, including a portion of the longitudinal sinus 7.5 cm. in length, to remove the entire tumor mass. The patient made an excellent recovery and was able to leave the hospital in six weeks. During the five months since that time he had worked hard on the farm and suffered no discomfort at all, except an occasional pain in his lower extremities. There was no evidence of recurrence. The tumor appeared to have originated from the injured pericranium and to have infiltrated the bone. From the microscopic examination the tumor was a fibrosarcoma, with some epithelial pearls and much hyaline degeneration present.

The Empyema Problem.—Dr. EMIL G. BECK of Chicago in his paper answered the following questions: (1) How should we explain the unusual virulence and high mortality of pneumonia and empyema? The causative factor was not definitely known. An ultramicroscopic and filtrable microorganism had not yet been demonstrated. The influenza bacillus might prepare the body for the pneumococcus or streptococcus infection. Lack of immunity against a new type of organism might be the cause. Robust adults were more susceptible than children and old people. Alcoholism, chronic bronchitis, or asthma were not disposing factors, rather the contrary. (2) How should we recognize an empyema early? Stereoroentgenograms would corroborate the diagnosis very early. Unresolved pneumonia with fluid accumulations was not empyema. The fluid must be purulent before it was regarded as empyema. Puncture with the needle cleared up the diagnosis definitely, but this was not without danger. (3) How should we differentiate an empyema from a lung abscess? Lung abscess appeared later than empyema, was centrally located, and localized by stereoroentgenograms. If it ruptured into a bronchus, the diagnosis was absolutely clear. Lung abscess and empyema might coexist. (4) What other means, aside from operation, might be employed to cure empyema? Repeated puncture and withdrawal of small quantities of fluid might cure empyema. Injections of formalin and other substances were not being advocated in the acute stages. (5) How soon should we proceed with an operation after we had made a diagnosis? No operation should be performed in the very acute stages when the fluid was still serous. A few ounces of the fluid might be removed by puncture to relieve distressing symptoms; drainage was to be reserved when the secretion was distinctly purulent and would furnish about 50 per cent. sediment in twenty-four hours. (6) What operation was the most desirable, resection of a rib or drainage between the ribs? Local or general anesthesia? (7) What method of drainage should be introduced? Introduction of a catheter through a cannula at the lowest level posteriorly most desirable. Withdrawal of two or three ounces daily without allowing any air to enter into the cavity was the best treatment. He advocated a counter-drainage in the lowest part of the cavity anteriorly, passing a catheter through both openings. If resection of rib was done, it should be the eighth or ninth rib posteriorly. This afforded best drainage for the patient sitting, standing, or lying down. Local anesthesia was advocated in all cases. (8) What should be done to produce disinfection and closure of the pleural cavity in the shortest possible time? Irrigation with Carrel-Dakin solution was advised for the first few days to dissolve fibrinous adhesions. Further irrigation was discontinued, if possible,

and spontaneous dry drainage was allowed to follow. (9) What were the causes of non-closure of the drained empyema? Injections of bismuth paste would close 80 to 90 per cent. of the cases if employed properly. A mixture of oil and bismuth was dangerous because the bismuth subnitrate would settle in the most dependent crevices in a few hours, from which it might be difficult to remove and thus cause bismuth poisoning. The bismuth in a vaseline mixture would precipitate and thus would not be dangerous. (10) What should be done with chronic suppurative cases with sinus or lung abscess or empyema which had persisted in spite of treatment? Skin sliding flap operation was reserved for these cases, since it was much easier and less dangerous and more effective than the Estlander and similar procedures. Before incising the skin a rubber catheter was introduced into the existing sinus and kept there as a guide during the first part of the operation. The skin incision depended upon where the abscess of empyema was located. He had employed three different types, the Y-shaped, the X-shaped, and the trap-door incision. Each of these incisions formed one or more flaps of skin, which were intended for inversion into the lung abscess after it had been exposed. From three to five ribs overlying the abscess cavity were then resected, as seemed necessary to expose the lung abscess to its full extent. A small incision of the thickened pleura was made along the catheter, the finger was introduced into the abscess cavity, and the cavity explored. The incision of the pleura was extended upward to the highest point, without cutting into the lung, and then the cavity was fully exposed to ocular inspection by removing as much of the parietal pleura as possible. In most cases of chronic empyema the lung would be found retracted upward and inward. At times the apex would contain functionally normal lung. In the cases of lung abscess, however, the matter was different. The globular or multilocular cavity, with thick septa, existed into which frequently opened one or more bronchi. In one of his cases seven bronchi opened into one lung abscess. The cavity being exposed, it should be swabbed with dry gauze, rubbing it roughly or even resorting to a mild curettage. This was done for the purpose of producing a favorable condition for adhesion of the skin flap. The cavity being dry, the tips of the skin flaps were drawn into the very deepest recesses by means of forceps. Gauze was packed tightly against them to keep them in contact with the raw surface of the abscess cavity. The denuded surfaces from which the skin flaps were taken were then covered with sterile gauze and no attempt was made to reduce the size.

The Surgical Complications in 1,030 Cases of Influenza.—Dr. C. J. ROWAN of Iowa City stated that the 1,030 cases of influenza in which arose the surgical complications to be considered occurred in the student body of the University of Iowa during the month of October, 1918. The barrack life of the Students Army Training Corps was responsible for so many cases among a student population of slightly over 3,000, and permitted an early and close observation of the cases. Of the surgical complications empyema was the most important, which occurred only in the pneumonia cases, of which there were about one hundred, and which was the cause of death in each of thirty-three fatal cases. Appendicitis was not a common complication. Many of the patients had the gastrointestinal form of influenza, and in quite a number of these there was finally pain, tenderness, and rigidity localized in the right lower quadrant. This was marked enough in some cases to have led to the diagnosis of acute appendicitis and to have indicated operation in ordinary times, but he felt that it was extremely important to avoid unnecessary operations in these influenza patients, that the involvement of the appendix was only a part of the enteritis of influenza; that recovery would take place unless secondary infection of the appendix occurred, and that secondary infection would be shown by the development of leucocytosis. Two of the patients did develop leucocytosis, showing respectively 14,000 and 18,000 leucocytes. As soon as it appeared, appendectomy was done in each case under gas and oxygen anesthesia. Whatever the primary cause of the influenza might be, the bacteria mostly concerned in the complications were pneumococci and streptococci.

Carcinoma of the Small Intestine.—Dr. E. S. JUDD of Rochester, Minn., said that in reviewing their records he found five cases of primary carcinoma of the duodenum. In one of these cases a gastroenterostomy was done for an inoperable obstruction which relieved the patient for a time. At autopsy, several months later, pathologists reported carcinoma of the duodenum extending up to the pylorus. In the second case there was a carcinoma of the pyloric end of the stomach, and beginning just above the pylorus, independent of the pyloric tumor, was a malignant papilloma of considerable size. In the third case, the original tumor was presumably of the first portion of the duodenum, although the ampulla was obliterated, and from the extent of the trouble it was difficult to determine at what point it originated. The fourth case was quite similar to the third and was an extensive malignancy. The fifth case was a large carcinoma originating in the first portion of the duodenum. Primary carcinoma in the region of the ampulla, if it obstructed the biliary and pancreatic ducts, presented the same clinical picture, no matter where the growth originated, namely, painless jaundice and great emaciation. Carcinoma in the mucous membrane of the ampulla was the most frequent type, and also probably offered most in the way of treatment. Carcinoma in the infra-ampullary part of the duodenum occasionally occurred as a primary constricting lesion. Such cases were often diagnosed as instances of pyloric obstruction, although the clinical features were different in that the patient with duodenal cancer and obstruction usually vomited a large amount of material which contained bile and pancreatic secretion. The tumors were usually small and produced a marked degree of obstruction. Carcinoma occurred in the jejunum either as a degenerated polyp or as a ring carcinoma, quite similar to the ring carcinoma frequently seen in the large intestine. These tumors rarely became so large as to interfere with the lumen of the intestine. Carcinoma of the ileum occurred in the annular contracting, or ring, type, also as a sprouting polyp or carcinoma, in which case the growth was a broken-down papilloma. Comparatively few carcinomas had occurred at the ileocecal valve. In nearly all of the cases the lesion originated several inches from the valve and was not associated with it in any way. In the present review were twenty-four cases collected from the records of the Mayo Clinic. The records also showed that during the same period there were 1,689 cases of carcinoma of the stomach and 1,822 cases of carcinoma of the large intestine. As compared with twenty-four cases of carcinoma of the small intestine, this would seem to be a smaller percentage than had been reported in other statistics. They had had eleven cases of carcinoma of the jejunum; the average age of the patients was forty-six years. They had had six cases of carcinoma of the ileum and the average age of the patients was fifty. In four of the six cases of carcinoma of the ileum the symptoms were of short duration, being present from one to twenty-one months. They had had two cases of multiple carcinoma of the small intestine, one of which died from pulmonary embolism following operation and the other died following operation. At the autopsy there was revealed a papillary cystadenoma of the jejunum, which was removed at operation; a papillary cystadenoma of the duodenum, cirrhosis of the liver, cholangitis and chronic cholecystitis of the strawberry type with papilloma.

Dr. ARTHUR DEAN BEVAN of Chicago said that he had had no case of primary carcinoma of the duodenum which had been recognized as such and operated upon. He had, however, had a number of cases of primary carcinoma of the small intestine—that is, in the upper jejunum—and they had presented some very interesting problems, both from the standpoint of diagnosis and of therapy. Carcinoma of the small intestine gave much the same picture as a pyloric obstruction, but some points were very different, one of which was the vomiting of a large amount of material that had accumulated in the stomach and entire jejunal loop. Another thing was attacks of partial obstruction resembling very greatly the partial obstruction that one had in the large intestine which had been temporary and recovered from, but which had been fairly acute. As to the diagnosis, one could make it with much more certainty

by means of the *x*-ray than any other way. As to therapy, he had given up the idea of making an end-to-end anastomosis in these cases. A lateral anastomosis was three or four times safer for the patient in these cases of carcinoma of the small bowel. Carcinoma of the small intestine, when early diagnosed, gave a favorable prognosis. He had three cases that had been well for a number of years after circular resection for carcinoma of the small intestine.

Are We Justified in Removing a Comparatively Healthy Gall-Bladder?—Dr. W. H. MAGIE of Duluth, Minn., said that his experience was based upon 300 operations upon the gall-bladder and bile ducts. There was no department of surgery in which there was a greater difference of opinion than in surgery of the gall bladder. He made a plea in favor of saving the gall bladder in at least a majority of the cases. He had never seen an empty or collapsed gall bladder when examining it during the course of operations in the upper abdomen. The fact that it was always filled with bile went to prove that it had much to do with keeping up and regulating the pressure in the bile ducts and liver. This theory was supported by the results of experiments upon animals. Eisendrath and others had shown that when the gall bladder was removed in dogs the remaining cystic duct dilated, as did the common and hepatic ducts. The dilatation of the cystic ducts took on the appearance of nature making an effort to reproduce the gall bladder. This same dilatation of the cystic duct had been observed in man after cholecystectomy. This effort of nature to reproduce the gall bladder was evidence that the gall bladder not only had the function of storing bile, but also had a pressure regulation function upon the biliary system. These facts should be taken into consideration where the question of cholecystectomy versus cholecystostomy was to be decided. In his early experience, before we were removing as many gall bladders as we were now, he was astonished to see a great majority of the empyemic gall bladders get well and stay well after drainage. If such results could be obtained from empyemic gall bladders, we could expect a mildly diseased one to recover and become again a functioning organ. It was generally conceded that cholecystectomy had a much greater mortality than cholecystostomy. If so, this consideration should bear weight in making up our decision. He had had no mortality in his cholecystostomies, while his mortality following cholecystectomy had been about the average mortality, if not greater than that of other surgeons. His cholecystostomy cases had not required reoperating in more than 5 per cent., and in every case where reoperation was necessary it was on account of overlooked stones or structure of the cystic duct. When should cholecystectomy be resorted to? (1) In all cases of hydrops with structure of the cystic duct. (2) Many cases of acute gangrene or threatened gangrene of the gall bladder. (3) All cases complicated with embedded stones in the cystic duct with ulceration produced by contact with the embedded stone that when healed would probably cause stricture. (4) All very thick walled gall bladders due to fibrous or calcareous degeneration. (5) All cases of ulceration due to pressure of large stones. (6) In cancer of the gall bladder where the disease was limited to the gall bladder.

Factors Which Determine the Relative Degree of Cure in Biliary Surgery.—Dr. B. B. DAVIS of Omaha believed the following to be the most frequent causes of lack of complete relief: (1) Impediments, as the result of structures, torsions, and lessened elasticity of the common or hepatic ducts to the free passage of the bile to the duodenum. (2) Lack of elasticity and contractility of the gall-bladder wall, resulting in stagnation of the bile in that viscus and continuous infection, and a tendency to reinfections. (3) Adhesions of the gall bladder to the pylorus, transverse colon, omentum, and liver. (4) Stricture or kink of the cystic duct. The avoidance of postoperative distress in all cases was more than one could reasonably expect. The amount of pathology present before the operation might be too great to permit complete restoration of function, but he believed care and skill would count a great deal in preventing or mitigating postoperative symptoms. In his early work he had occasionally removed the gall bladder because of pathology which seemed too extensive to permit of a continuance of normal function. It was early noted that many of these cholecystectomies produced more complete relief than the less radical cholecystostomies. He had been gradually led to the conclusion that a large part of postoperative distress was due to gall-bladder adhesions, and that if we could avoid these adhesions postoperative distress would be greatly lessened. Efforts at more careful handling were redoubled, but with only slight improvement in results. The gentlest handling of the gall-bladder peritoneum seemed often to produce dense adhesions. The only effective way to avoid pericholecystic adhesions was to remove the gall bladder, and he believed this was the most potent argument in favor of indiscriminate cholecystectomies. Surgeons had been compelled to resort to this measure because of the very unsatisfactory results following the more conservative operation. If any effective means could be found for preventing post operative adhesions, most of the gall bladders now removed could be profitably retained.

Fracture of the Skull; Diagnosis, Treatment, and End Results.—Dr. W. D. HAINES of Cincinnati, Ohio, said that head injuries were prone to take their toll either immediately or at some future time. The former would entail shock, hemorrhage, and fracture, while the latter would find expression in persistent headache, abscess formation, epilepsy, or insanity. The great discrepancy between the clinical findings, symptoms manifesting, and the extent of fracture was well illustrated in the case of a patient, a man thirty-four years of age, powerfully built, and slightly demented, who was confined to a private sanitarium. During the momentary absence of his attendant the patient butted his head repeatedly again the radiator. When admitted to the hospital a few hours later the patient was rational, answered questions promptly, and expressed regret that he had not succeeded in destroying his life owing to his disordered mental state. The temperature, pulse rate, and respiration were little at variance with the normal, notwithstanding the presence of multiple, extensive fracture of the vault, with one large detached triangular piece of bone driven some distance into the substance of the anterior part of the left lobe of the brain. Uneventful recovery followed removal of the depressed fragment. Some of the most extensive and fatal brain and cord lesions had followed injury wherein no fracture was found in the ward, *x*-ray room, or dead room. Skull fracture patients were almost without exception suffering from some degree of shock, ranging from slight depression to profound unconscinusness when admitted. Infinitely more good would be accomplished for the patient by employing measures to relieve shock than by immediate operation, the one exception being the presence of active hemorrhage, and even here there was room for argument. Linear fractures of the skull without displacement would require evidence other than that obtained by palpation in their recognition. In suspected cases wherein the *x*-ray was not available, exploration or lumbar puncture, preferably the latter, would aid in establishing the diagnosis. Percussion was of value in such instances, but evidence thus obtained should be confirmed. Shock and altered reflexes entered into the scheme of diagnosis and must be given careful consideration in determining the management of the patient. Pressure symptoms were the most insistent for relief. Their presence, extent, and gravity might be very accurately determined by studying the fundus of the eye. Notwithstanding the desperate conditions embodied in fracture of the base of the skull, about 50 per cent. of the patients surviving the first forty-eight hours following receipt of the injury made a final recovery. The treatment should be directed with a view of relieving shock, stopping hemorrhage, preventing infection, and controlling pressure.

Volkmann's Contracture.—Dr. E. M. Sanders of Nashville said that when patients presented themselves for treatment and the diagnosis was made of Volkmann's contracture without complications, there were three avenues open to the surgeon: (1) The method of Jones, where gradual extension was applied to the fingers and wrist by a specially prepared splint, using progressive extension from time to time, accompanied by vigorous active and passive motion, hot applications, and electricity. Mild cases could be satisfactorily managed by this method. Sayre and others had used this line of

treatment with good results. He had used it with surprisingly good results in some cases and all were greatly benefited. The value of this method of treatment depended largely upon the promptness of its application, the co-operation of the patient, and the persistence with which it was carried out. (2) The more severe cases could not be so treated with any degree of satisfaction, and should be subjected to the operation of tenoplasty, where elongation of the tendons of the affected muscles was accomplished by using the LL incision on the tendons. This should not be done earlier than three months from the establishment of the contracture, as it took about this length of time for the maximum damage to be done. In treating these cases one should never overlook the necessity of capsulotomy, where the anterior capsule of the wrist joint was permanently contracted. (3) In the more severe cases, and especially in children, resection of both bones of the forearm, as done by Mikulicz, was justified and had given a fair percentage of good results in apparently hopeless cases. Before either of these operations was advised, one should remember the increased risk of infection because of the deficient nutrition of the parts, and the resulting adhesions between the tendons, and where the bones were dealt with also the danger of nonunion and deformity. The prognosis should be guarded, as the end results were apt to be far from ideal. As a rule, surgeons were in too great a hurry to reduce fractures and apply dressings, and this was especially true of fractures of the forearm and about the elbow in children.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Miscellany.

Forensic Medicine in Lima, Peru.—The medical profession in the South American States seems to us to show an unusual interest in forensic medicine, which is praiseworthy but not altogether intelligible to us. Rather perhaps our own indifference to the subject is what should really be hard to understand. We have repeatedly called attention to this tendency in the MEDICAL RECORD. Bahia has apparently a unique research institute devoted to the subject of forensic medicine, and the medical societies which exist in Brazil and elsewhere for the prosecution of these studies have a membership of high order. Many student theses are devoted to subjects which belong under legal medicine. In this connection, therefore, it will be of interest to abstract an article from the May-June number of the *Anales de la Faculdad de la Medicina* of the University of Lima, from the pen of Dr. Avendaño on the history of legal medicine in Peru. In 1570 a bull of Philip II was responsible for the institution of a tribunal for the solution of medicolegal questions, whether administrative, civil, or criminal. This tribunal was not suppressed until 1851. In the sixteenth century it was occupied chiefly with inhumation and embalming; in the following century sudden death was the dominant subject and in the eighteenth, abortion and abortifacients, which led to many autopsies. During the entire period sexual aberrations and rape were frequent and received due attention. In the nineteenth century the individual subjects began to be more numerous and varied and a more scientific tone is in evidence; so that eventually a so-called scientific "morgue" with a laboratory annex for toxicological work came into existence. This institution was initiated in 1889-1891, and in 1897 a refrigerating plant was added. But this did not satisfy the ambitions of the Peruvians, so that the present "morgue" is virtually a new institution. It takes charge of the cadaver and identifies it. All resources for preservation are available, so that delay cannot defeat justice. Autopsies are conducted with all accessories in the building—there is no need to send off specimens and exhibits to this or that remotely seated expert. The morgue is also a center of police activity and serves for the instruction of the university medical students. Credit for the scope of the institute is said to be due in part to the ideas of Professor Zangger of Zurich who has long advocated such a centralization and affiliation of activities. But the idea strikes us as quite like that of the Nina Rodriguez Institute of Bahia, which while operated by a foundation is partly under the control of the State.

Curative Vaccination of Influenza.—Cépède has attempted to treat this affection with a vaccine made from mixed cultures of the pneumococcus, streptococcus, and enterococcus. This vaccine is carefully prepared, and standardized at 100,000,000. The minimum dose is 1 c.c. He alleges favorable results in three cases of influenza in children. Although the paper was read before the Academy of Sciences, the reporter seems very sceptical, as the author recently announced the discovery of a curative vaccine for tuberculosis.—*Le Progrès Médical.*

SYPHILIS AND PARASYPHILIS OF THE CENTRAL NERVOUS SYSTEM; DIAGNOSIS, PROGNOSIS, AND TREATMENT.

By M. NEUSTAEDTER, M.D., Ph.D.,

NEW YORK.

LECTURER IN NEUROLOGY, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MED. COLLEGE.

With the advent of the Wassermann reaction in the diagnosis and salvarsan in the treatment of syphilis in its various manifestations, a reconsideration of our knowledge of the histopathology of the various forms of the disease and their clinical phenomena becomes imperative, since the question of diagnosis is of paramount importance.

In a discussion of the differential diagnosis of cerebrospinal lues, tabes, and paralytic dementia, we must take due cognizance of the histopathology of syphilis in its relation to parasyphilis and its probable modus operandi in giving rise to the respective symptom complexes. It is only upon such basis that one can venture to discuss reasonable prognosis and a rational treatment.

Syphilis of the central nervous system manifests itself as the tertiary type in: (1) vascular involvement, (2) gummatous exudates in the meninges, (3) gummatous deposits in the substance of the brain or cord, and (4) the so-called paraspyhilitic affections.

1. The vessels may suffer through the mechanical pressure exerted upon them by the syphilitic deposits of the meninges or nerve tissues surrounding them, thus giving rise to an obliterating endarteritis or phlebitis. The syphilitic inflammatory process may involve the vessels through contiguity, involving the outer coats first, and give rise to a periarteritis and later to a mesoarteritis and a panarteritis. And finally the vessels may become diseased as a result of the direct influence of the syphilitic virus by its irritation of the vessel walls and the consequent inflammatory reaction. The adventitia and media become involved first and the intima secondarily. The endothelial cells proliferate first. The vasa vasorum become inflamed and a proliferation of the connective tissue cells in the adventitia, followed by deposits of round cells into the new formations of the intima. The proliferation of the intima may continue until the lumen of the vessel is partially or totally occluded. This form of vascular change is most commonly met with. Partial or total occlusion may also be brought about by thrombosis. As a result of this obliteration we have a complete or partial absence of nutrition of the parts supplied and, of course, there ensue a necrosis and softening. Although the vessels of the base as well as those of the convexity of the brain may become affected, the softening of the cortical areas and those immediately at the base are usually not affected in as marked a degree as the more remote parts in the interior of the brain. The reason for this is the fact that at the base and convexity a collateral circulation is easily established, while in the interior there are chiefly end-arteries without anastomoses. This is especially true of the internal capsule, the pons, and medulla. And it is quite common to have areas of softening in these places as a result of vascular involvement. Hemorrhages into the brain and cord as a result of this form of periarteritis and endarteritis are not uncommon although rather rare. The tears of the vessels result where the elastic tissue becomes rather thinned and the muscularis of the adventitia is supplanted by a less resistant connective tissue. A high blood pressure will under such conditions break the vessel wall and the blood will exude into the neighboring substance.

2. The meninges of the brain and cord are more frequently involved than the vessels. The contiguous parts may or may not be affected in this process. This is due to the vascular and lymphatic richness of the leptomeninges. The syphilitic virus and toxin find their way into them through the circumambient fluids. The gummatous, gelatinous exudate deposited here frequently involves the contiguous dura which becomes adherent to the soft meninges forming one thick covering. The underlying nerve substance may become affected in the same way and give rise to a meningomyelitis or meningoencephalitis as the case may be. Single meninges may at times become involved alone. Sano describes a case of what he terms a syphilitic arachnitis. The arachnoid in this case had the gummatous exudate on its outer surface and thus the inner surface, the pia, and the brain tissue of the frontal lobe were spared. Lang even mentions a specific hyperemia of the meninges of the cord, especially when the spinal cord symptoms are of a transient type. I can report a similar case. It is of course conceivable that a hyperemia should accompany a specific inflammation.

The meninges of the convexity of both hemispheres are preeminently affected in specific processes, especially those of the frontal and temporal lobes. Next in order those at the base involving the olfactory nerves and continuing to the optic chiasm and even far down into the cord. Finally there have been observed isolated syphilitic meningitides of the various parts of the cord. The more frequent affection is the dorsal region, the cervical and lumbar not as frequently. (Fig. 1.)

In accordance with the site involved we speak of a syphilitic meningitis of the convexity, a basillar, and a spinal. The pathological character is the same in every instance. The microscopical picture discloses an extensive infiltration of round cells and a thick-

Fig. 1.—Spinal syphilitic leptomeningitis, dorsal segment. Gummatous infiltration around the whole cord. Destruction of the posterior horns and part of the columns of Burdach.

ening of the meninges with specific alterations of the vessels. The infiltration is especially marked in the neighborhood of the smaller vessels which are usually present in large numbers in the meninges as well as in the contiguous tissues. (Fig. 2.) In places this infiltration takes the shape of miliary gummata; as a rule, however, there are extensive deposits within the subarachnoid space and in the course of time this exudate becomes organized through the deposit of connective tissue, the meninges becoming firmly adherent. The gummatous deposits are here seen inclosed in meshes of connective tissue. At times extensive hemorrhages are found to accompany such process.

3. Gummatous deposits into the brain and cord substance, as already previously stated, are as a rule a constant accompaniment of a specific meningitis. But there are cases on record where the syphilitic process affected these parts primarily. In the cord the process continues along the septa, the pial indentations and the vessels; in the brain, however, through the latter mainly. The progress is rather slow and insidious, and for this reason this affection of the central nervous system can be termed chronic meningomyelitis, or meningoencephalitis as the case may be.

In the case of the spinal syphilitic affection the process is not equally distributed, for at one time the posterior and at another time the lateral aspects are predominantly involved. (Fig. 3.) It is only late in the disease that the entire circumference is affected and then we find the cord completely enveloped in the thickened membranes. This is also true of particular segments. As a rule the dorsal segments are more often affected, at times the lumbar alone, and the cervical are as a rule the followers of a basal encroachment. The myelitic process, however, is less extensive than the meningeal. Even in cases where the entire cord is affected we find only disconnected and widley disseminated foci. Microscopically we note infiltration with small granulation elements in their center and numerous small vessels with specific changes in their walls. In other instances we note gummatous infiltrations starting from the meninges and wedging themselves into the cord tissue. These new formations appear as enormous round cell deposits. In the neighborhood of this infiltration the contiguous tissue loses its cell elements and there appears a proliferation of glia cells which seems to inhibit a further extension of the syphilitic process. Later on the infiltrated tissue is replaced by fibrous deposits and the vessels present a hyaline degeneration or are completely obliterated. The process involving the brain is quite analogous to that of the cord and a repetition seems unnecessary.

4. The parasyphilitic affections of the central nervous system are those which yield the symptom-complexes of tabes, taboparesis and paralytic dementia. As in the syphilitic alteration of the tissues we have here as well meningeal, vascular, and parenchymatous changes. The all-important question is whether the neuron decay is primary or secondary to destruction of other tissues or simultaneous with them.

The histopathology of tabes is characterized mainly by a progressive degeneration of the nerve fibers of the posterior columns and a marked proliferation of the glia. The nerve fibers lose their myelin sheath, they swell up, the axis cylinders atrophy and the whole fiber becomes destroyed. The proliferated glia appears as a fine fibrous meshwork within which one frequently discerns the empty spaces of the destroyed nerve fibers. Later on this is changed into connective tissue in which numerous nuclei, spider cells, and amylaceous bodies are to be found. The vessels are always showing changes. Their walls are thickened and hyaline, the lumen is contracted, and here and there is a considerable interstitial or perivascular infiltration of cells. The same degenerative and atrophic changes are to be seen in the posterior roots at times of a varying intensity in different places of the fiber alongside a corresponding proliferation of the connec-

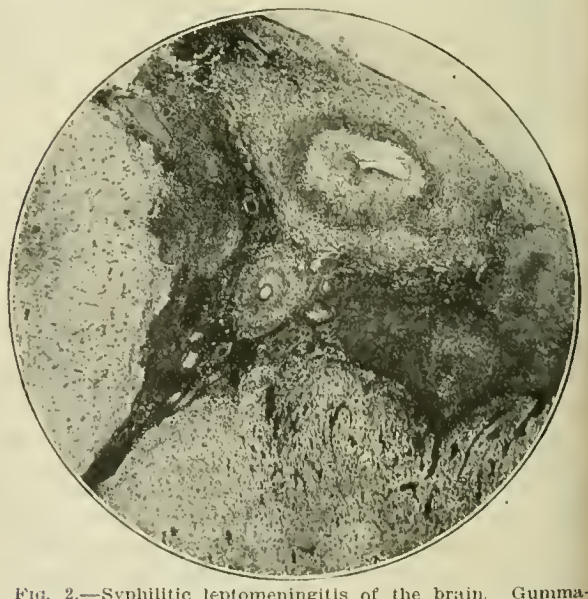

Fig. 2.—Syphilitic leptomeningitis of the brain. Gummatous deposits around the pial vessels. Infiltration around the vessels of the contiguous parts of the brain substance. Specific endarteritis of the vessels with partial occlusion of the lumen.

tive tissue and thickening of the vessels; here and there also a considerable small cell infiltration. This is rather positive evidence that we are dealing with a primary neuronic degeneration, and that the proliferation of the glia is secondary. Yet the whole

process cannot be distinguished from the secondary ascending degeneration of the nerve tracts.

Of great importance is the localization of the process in the posterior columns. This begins, as a rule, in the lumbar segments with a symmetrical

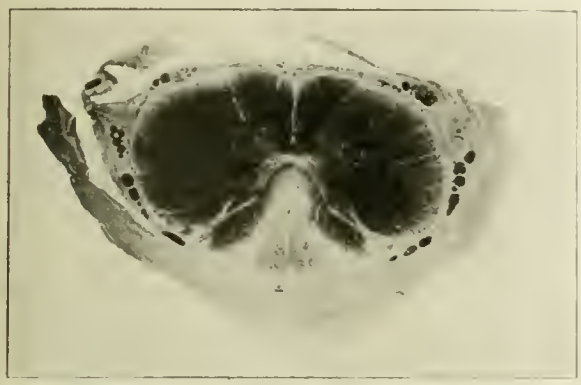

Fig. 3.—Spinal syphilitic leptomeningitis. Lower cervical segment. Posterior part more involved and to some extent the lateral part of the pia and arachnoid on one side. Columns of Burdach completely gone.

involvement of the columns of Burdach, which degenerations are seen in the same subject to embrace the columns of Goll in the higher segments. The more segments show an involvement of the columns of Burdach the greater the amount of degeneration of the columns of Goll above. A very careful examination of sections shows that the fibers nearest to the root zones are always affected. The cells of the posterior horns and of Clark's columns are never affected, and those of the intervertebral ganglia rarely show any changes. The whole process then is limited to the sensory neuraxon centripetally from the ganglion cell in the intravertebral ganglion. The meninges show a thickening and adhesions, and in some cases even a decided specific leptomeningitis. Among the French authors, Nageotte, Dejérine and Thomas, lay particular stress upon this mild form of meningitis as decidedly syphilitic. The neuraxon distally from the ganglion cell is rarely, if ever, degenerated, although degenerations of the peripheral nerves have been met with. With the exception of the oculomotor, the motor cranial nerves are rarely degenerated. In cases of pronounced syphilitic leptomeningitis the characteristic posterior root and column changes are evident the same as in tabes. Obersteiner and Redlich reasoned from this analogy that the thickened pia around the posterior roots is constricting them, and thus causes a symmetrical degeneration. The pial changes are, however, so mild that this theory is rather untenable. Nageotte, however, found a lesion in the nerve roots centrifugally to the spinal ganglion that is always present. This is an interstitial transverse root neuritis (a perineuritis and endoneuritis with interstitial and parenchymatous changes), whose starting point is a mild form of chronic syphilitic meningitis, and which is conditioned by the lymph channels in its distribution. This root neuritis is also syphilitic in character. According to his theory, the tabetic changes are always preceded by a diffuse syphilitic meningitis of the pia characterized by a thickening and a diffuse or focal cell infiltration, with specific vascular changes in the arteries and capillaries and also in the vein. This is well substantiated by the lymphocytosis which is always present in the spinal fluid. But he insists that tabes is produced by the root neuritis, and that the pial and vascular changes are concomitant manifestations of the same process. The motor root in the proximity, although somewhat higher up, is also affected, but has a peculiar tendency of regeneration. Without entering into an extensive discussion of Marie and Guillain's theory of a lymphangitis, and Thomas and Hauser's theory of a primary neuronic degeneration, I am inclined to accept Nageotte's findings as the most rational, namely, a postneuritic degeneration, and therefore a primary neuronic degeneration. The vascular changes may, after all, be a reaction with a tendency to repair.

In the paralytic dementia we find the same histopathological changes as in the tabes; here, of course, a meningoencephalitis. Most authors agree, and for good reasons, upon a primary neuronic degeneration. The vascular lesions may at times predominate, but it was not shown that they were the primary condition.

From the above description it would seem evident that there is a general similarity in the lesions of general paralysis and tabes and other syphilitic lesions; namely, there is an endothelial and conjunctival hyperplasia, with a tendency to fibrous and sclerous formation. In tabes and paresis there is also the primary neuronic decay which we cannot readily account for solely by the changes in the supporting, inclosing and nutrient tissues, as we can in syphilitic lesions. Noguchi and Moore, and, later, others have demonstrated the presence of the *Treponema pallidum* in the tissues of the central nervous system in the parasyphilitic affections, and the Wassermann reaction is positive in all cases in the cerebrospinal fluid and the blood serum. While the blood in cerebrospinal syphilis, as a rule, gives a positive Wassermann, the spinal fluid is not

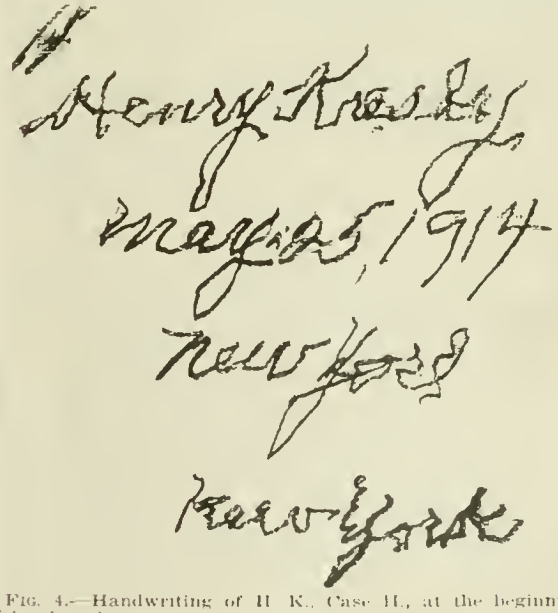

Fig. 4.—Handwriting of H. K., Case II., at the beginning of treatment.

always positive. The reason for this is that the globulin present in the blood cannot pass through the cerebrospinal vessels which are affected by an endoarteritis and periarteritis, into the cerebrospinal fluid. While in the parasyphilitic affections

the globulin necessary for the Wassermann reaction comes from the degenerated neurons of the cerebrospinal axis. This is illustrated by the fact that the fluid from the ventricles is about ten times weaker in linking up the complement than the spinal fluid. But I want to lay emphasis on the fact here that these rules do not obtain in all cases, and yet the symptom-complexes are those of tabes, general paralysis, and taboparesis. It is held by Mott and others, for quite rational reasons, that antispecific treatment in parasyphilis is of no avail. Yet we have recent reports of cases that disprove this theory by the fact that patients have been markedly improved and the Wassermann reactions of the blood and spinal fluid, as well as the lymphocytosis, have disappeared. It must, however, be pointed out that in some of these improved cases relapses led to death with characteristic postmortem findings. A few of the cases that came under my observation may be of significance:

Case I.—T. B. D., æt. 48, male, colored, waiter by occupation. Venereal and alcoholic history positive. Initial lesion 20 years ago without secondaries. About a year ago he developed a marked loss of memory characterized by forgetfulness, inability to compute most simple mathematical problems, forgetting to take change when making a purchase, taking the car in wrong direction when on way home from work, becoming erratic and confused in his statements, exhibiting expansive ideas, very excitable and abusive without provocation although a very meek and tender husband before. He suddenly took a notion that he ought to stop working and went to Washington to visit his relatives with whom he had not communicated in 15 years. He left New York with $200 and arrived there penniless. On inquiry he did not remember what he did with the money, but subsequently it was discovered that he squandered it upon strange children, inducing them to accept all sorts of things. In my attempt to persuade him to come home he at first seemed inclined to go with me, then he would want to go to all sorts of places, and finally refused to go and became quite abusive. He had to be forcibly committed to an asylum.

His physical condition was as follows: He was well nourished, although he lost considerable weight within the last two months, about 20 pounds. He had an Argyll-Robertson pupil, eye fundi normal, a slight Romberg, some ataxia in the upper extremities, exaggeration of all reflexes, a marked, fine intention tremor in hands, lips, and tongue. His speech was drawling, but not to any extent. There was a considerable hypalgesia in the lower extremities and some delayed sensation. The Wassermann reactions of the blood and spinal fluid were strongly positive. There were 20 cells in the c.c., globulin and albumin strongly positive. There is no doubt that this is a case of taboparesis. In this diagnosis I was confirmed by the authorities in Washington, Bellevue psychopathic wards, and Manhattan State Hospital, where he was ultimately confined for three months. His condition slowly improved and he was liberated on parole after the time mentioned. I have since subjected him to an intense antiluetic treatment, salvarsan alternated with potassium iodide and intramuscular injections of mercury for the last five months with excellent results. His memory, especially the retentive memory, is very good, he is perfectly rational, goes in the usual manner about his business, is very docile, never irritated, is sorry for the manner in which he behaved toward me, gained 25 pounds in weight, and is very cheerful. His physical status at present is as follows: The Argyll-Robertson pupils are still there, there is no Romberg and no ataxia in the upper extremities, the tremor is slight and in hands only, the reflexes are present but not very brisk, the fundi oculorum are normal, the speech is slow, and the hypalgesia is as before. The Wassermann reaction of the blood is still strongly positive. (After sending in this article the patient died of cerebral hemorrhage. Autopsy was not obtained.)

Case II.—H. K., æt. 23 years, male, salesman, of a negative family history. He denies venereal diseases and abuse of alcohol and tobacco. He was operated upon for trachoma ten years ago. Had a hydrocele of his testes some time ago, otherwise negative. Seven years ago his vision began to be blurred, but he did not pay any attention to this eye defect until a year later when he developed a diplopia. Then he consulted Dr. Weeks. Three years later his speech became rather slow and scanning and at times stuttering. In June, 1913, his blood gave a strongly positive Wassermann reaction. He was then treated with salvarsan, receiving five intravenous injections in intervals of five days followed by mercury intramuscularly. After the last salvarsan injection he developed a marked intention tremor in his hands with ataxia (Fig. 4), so much so that he was unable to hold a pencil or other objects and had to be fed.

In March, 1914, Dr. Weeks referred him to Dr. Fisher, with whom I have seen him, with a diagnosis of a double optic atrophy following an optic neuritis. His Wassermann of the blood and spinal fluid at this time was negative. There were six cells to the c.mm. in his fluid, all lymphocytes; globulin normal, and reduction test normal. He still had the diplopia with a paralysis of the right external rectus of the eye and lateral nystagmus. The pupils were unequal and reacted sluggishly to light, but well to accommodation. His gait was of the spastic paretic type. The abdominal reflexes were absent, the cremasters present, the patellar and Achilles reflexes were markedly exaggerated, ankle clonus was present on both sides, there was the extension toe reflex to the Oppenheim method on the right side only, no Babinski on either side. A few months after the first examination the Babinski reflex appeared on both sides. He was under our observation for two years and has received during that time alternately intramuscular injections of a soluble salt of mercury and iron arsenate.

He has steadily improved, his tremor is completely gone, his speech is fairly normal, there is no diplopia, his gait is excellent. The optic atrophy in the right eye is complete, the vision in this eye is limited to finger vision, while that of the left eye remained at a standstill and the visual field here is somewhat concentrically diminished. His Wassermann reaction is still negative. He has been employed for the last ten months as a clerk and writes as well as ever.

Case III.—C. H., æt. 30 years, female, married. Family history negative. Denies venereal diseases and alcoholism; she has given birth to five living children and never miscarried. She had exanthemata of childhood and pneumonia and recovered from all without sequelæ.

History of reported illness: Since April, 1915, patient began to suffer from stiffness of the neck and pain on motion. Gradually both shoulder joints, the elbows, and wrists became involved in the same manner. There was no swelling of joints. After a few weeks both hands became numb and pain increased in severity, becoming most intense at night. Toward the end of July there appeared edema of the legs, the right being first involved and accompanied by pain which was partially relieved on walking.

In addition to the above she now began to lose power and feeling in the arms and complained of numbness and pain in the right epigastric region. Soon loss of power manifested itself in both legs. This progressive involvement extended over the time between April and August, 1914, when she was still able to stand when supported. After August 14 she was completely paralyzed in the upper and lower extremities. Since the beginning of her illness she has experienced a burning pain on micturition and a difficulty in starting. Later on there was retention and she had to be catheterized. At times she would have incontinence and dribbling without being aware of it. Toward the end of July she began to suffer from a dull continuous headache. She had no difficulty with either vision, speech, or hearing. Off and on she would have difficulty in swallowing. In July, 1914, she gave birth to her fifth child after a normal and practically painless labor, especially during the entire second stage. She nursed her child until August 28, when she was admitted to Bellevue Hospital,

where I have seen her from time to time with Dr. Fisher.

Physical status on admission: Patient poorly nourished with a toxic facies but not suffering any particular discomfort. The pupils were irregular and unequal and reacted sluggishly to light but well to accommodation. Ocular fundi normal. All other cranial nerves normal. There was a complete spastic paralysis of both upper and lower extremities. There was an atrophy of the interossei and thenars of both hands and extensors of the forearm, especially marked in the right. There was also a slight atrophy of the muscles of the lower extremities. The chest was emaciated, abdominal muscles wasted, paralysis of the intercostals. Sensory disturbances: On passive motion of the head the patient experienced pain at all times in the region of the nucha. While touch sense was normal all over, the pain sense was markedly diminished and there was a complete thermanesthesia in the trunk, upper, and lower extremities. The deep muscle sense was retained. Reflexes: Elbow, radial, patellar, and Achilles exaggerated, abdominals absent, ankle clonus and Babinski were present in the right but not in the left foot. Corneal and pharyngeal reflexes were present.

On September 2 patient developed an area of complete anesthesia, beginning at the last dorsal and extending down the entire body. This sensory disturbance progressed rapidly upward and on September 18 there was a complete anesthesia up to the level of the third rib, except on the inner sides of the calf, where we found an appreciation of deep pressure sense rather than pain sense. The Babinski reflex and ankle clonus were now present on both sides.

A lumbar puncture was made on August 30 and 15 c.c. of fluid were withdrawn under normal pressure. The Wassermann of the fluid and of the blood taken on the same date was negative. There were 4 cells to the c.mm. in the fluid, globulin was negative, reduction test positive, and it contained a trace of urea. A vaginal smear was positive for gonococci. The radiographic examination was negative. The uranalysis showed nothing of importance.

A tentative diagnosis of a cord tumor was made and the operation was performed by Dr. Stewart on December 28, 1915. No tumor was found. Her respiration, which had become shallow and labored before the operation, improved somewhat after, but her general condition was unchanged and she expired on March 5, 1916.

Postmortem examination and histological findings are reported by Dr. Symmers as follows: The meninges covering the cervical enlargement of the cord for a distance of about 3½ cm. are thickened, especially on the posterior aspect. The thickening is largely confined to the leptomeninges and sometimes reaches 3 mm. in depth. Microscopic examination of the leptomeninges of the cervical region reveals great thickening due to the undergrowth of fibrillar connective tissue and to the presence of hyaline material. Embedded in the thickened meninges are large numbers of markedly distended, thin walled blood vessels, each of which is encircled by a thick layer of round cells. In occasional instances the vessel wall is thickened and in at least one instance the vessel shows the lesions incident to a well marked endarteritis obliterans. The meninges lying between the distended vessels are richly infiltrated by small round cells of the lymphocytic type. The meningeal prolongations into the cord are marked by the presence of enormous numbers of small round cells of lymphocytic type, and many of the smaller vessels in the substance of the cord itself show circumferential cellular infiltration.

Microscopic examination of a posterior root ganglion removed from the upper cervical region shows the following changes: At one point the periphery of the ganglion for a considerable distance shows the presence of overgrowth of fibrillar connective tissue, some of which has undergone hyaline transformation. The tissue for the most part is richly cellular, the cells being partly of the type of fibroblasts and partly of the type of small round cells of the lymphocytic variety. The substance of the ganglion itself shows scattered areas of hyalinization, small areas of necrosis, and foci composed of finely granular, pinkish staining substance in which rounded or cylindrical nuclei are to be made out. Many of the vessels embedded in the substance of the ganglion are thickened and some show the typical changes of endarteritis obliterans. At one point in the substance of the ganglion there is a focus made up for the greater part of small round cells with a sprinkling of epithelioid cells, and in the center is what appears to be a typical Langhans' giant cell.

Microscopic examination of the nerve fibers proceeding from the posterior root gnglion shows the presence of enormous numbers of small round cells lying in the perineurium as well as in the connective tissue septa between the individual nerve fibrils. The blood vessels in the perineurium are markedly distended, and all of them show a mantling of lymphocytes.

Microscopic examination of the smaller vessels at the base of the brain shows the presence of widespread hyaline transformation of the adventitia. The adventitia is diffusely and more or less abundantly infiltrated by small round cells. The muscle layer is apparently well preserved. The hyaline lamina is noticeably thickened, and the sub-endothelial connective tissues are irregularly but markedly sclerotic. Diagnosis: Syphilis of the meninges and of the posterior root ganglia of the cervical cord. (This case was reported by Dr. Fisher in the MEDICAL RECORD, June 24, 1916.)

A number of other cases of these types could be cited from my experience, but these may suffice. Some were treated with intravenous injections of neosalvarsan, and lately with novarsenobenzol, an equivalent of the former, one case with a combination of intravenous and intraspinous autosalvarsanized serum, and all followed by intramuscular injections of mercury and potassium iodide internally. While I am as yet unable to speak of cures, these patients were markedly improved. A small number were unimproved, and these evidently were cases with complete organic destruction, of whom Mott and other investigators speak as not responding to any treatment.

In conclusion we might say that all methods of determining which case is beyond help and which is still amenable to treatment are purely speculative, since no positive signs are available to diagnose that *intra vitam*. Since even in cases with markedly evident organic changes, as in tabes, many symptoms have been ameliorated, notably the various crises, and in paretic and taboparetic syndromes beneficial results were obtained, we are justified in treating every case along the well-established lines.

1215 PARK AVENUE.

MAJOR H. R. ALLEN'S INSTANTANEOUS METHOD OF RESHAPING TOOL HANDLES SO THAT THEY MAY BE USED BY DEFORMED OR CRIPPLED HANDS.

BY MAJOR R. W. SHUFELDT, MEDICAL CORPS, U. S. ARMY

ARMY MEDICAL MUSEUM, WASHINGTON, D. C.

OUR conflict with Germany accomplished at least one great end, and that is it americanized America. In doing this, it developed in us a vast store of latent energy that has already manifested itself in starting every wheel in the machine of creative genius. We held up our end pretty well in such matters before the war, but the crushing demand for inventions of all sorts; the meeting of the endless propositions that almost immediately presented themselves as a result of the country entering the war, and a great many other reasons—the stim-

ulation given to every conceivable public and private industry, and its far-reaching effects, now stands without precedent in human history. These various impulses and demands very promptly affected every department of medicine and surgery and more particularly the military side of them. At first the materials of all sorts for the means of offense and defense felt the result of the declaration of war against such a powerful and well-equipped nation as Germany was at the time, and all such materials are well within the sphere of observation for the surgeon and physician, and all call for their careful consideration.

Fig. 1.—Use of chisel carrying a plastic handle. Case: Pvt Hazel Asbury

After our troops became actually engaged at the front, still other problems arose, and these in the main involved the handling and treatment of the wounded and the subsequent care of the cripples. All this immediately made another tax upon our inventive genius, so that no end of improvement and new inventions came into being almost as rapidly as the demand called for them.

In this connection may be mentioned the many new models of artificial limbs; new types of stretchers; orthopedic appliances of many sorts and, in most instances, more efficient ones than those in use during the latter part of the last century, many of which were the old Civil War models—indeed, the improvements and inventions, in so far as they have referred to the materials and appliances used by physicians and surgeons, have been well nigh limitless.

Many of these constructive appliances have been examined and studied by me, since I came on duty early in January, 1918, at the Army Medical Museum in Washington. During the summer of that year, or perhaps a little earlier, the staff of that institution had added to it—among a number of other officers of the Medical Corps—Major H. R. Allen, whose home is at Indianapolis, Indiana.

Major Allen is an author and an authority in several departments of surgery, and especially in modern orthopædics. He has made many substantial improvements in the way of various appliances for the treatment of fractures, dislocations, and deformities, and it is the purpose of the present article to describe what I take to be the most recent of his ingenious inventions. Its application is far-reaching and makes for the very prompt improvement in the use of crippled hands, or in the deformities of those members.

My first opportunity to look into this matter occurred early in November, or late in October, 1918, when Major Allen kindly invited me to accompany him to the Walter Reed General Hospital, in Washington, where some moving pictures were to be taken of his above mentioned method of restoring the use—as far as possible—of crippled hands.

At the hospital, five privates and a corporal were ordered to report to the Major, each one of whom had been wounded in the left hand by some small missile or other at the front. The wounds were all healed, and the reason given for the injuries all being left-handed ones is that, in holding the piece, it is the left arm that is extended, which greatly increases the chance of the left hand being the one to receive the wound, while the right hand is usually next to the body close to the belt. This hand, if shot through, usually results in a fatal body wound with it. We could secure no men wounded in the right hand at the Walter Reed Hospital at the time we were there, which was unfortunate as it did not bring out, as it otherwise would have done, the great importance of Major Allen's reconstruction methods. However, handicapped as he was in this respect, he conducted the demonstrations at the hospital in an eminently successful and satisfactory manner. Subsequently the pictures were thrown upon the screen at the Army Medical Museum, and favorably passed upon by a number of orthopedic surgeons of distinction who saw them.

In all these cases the wounds were entirely healed with the best possible results, while at the same time, in all the cases, the grasp was so weak that the member was still practically useless. In no instance could a "fist" be made, and even to pick up such a tool as a hammer or a saw, was simply out of the question. Now all of these men were to be discharged from the Army, and would be thrown on their families or others as cripples, to be cared for and supported; so that any means or invention that would give the hand use during the recovery, and allow of the men earning their living in comfort would certainly prove to be a boon of the first class.

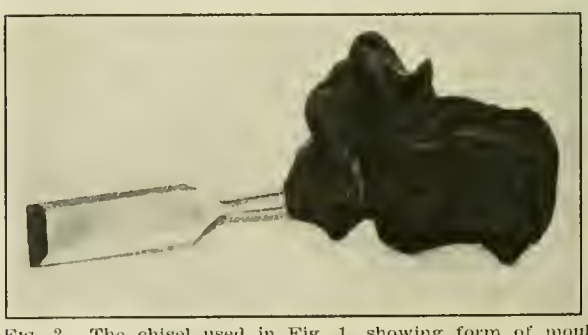

Fig. 2.—The chisel used in Fig. 1, showing form of mould and impressions made by fingers and palm of hand.

It is a fact well known to the surgeon as well as to the laity that, in order ultimately to gain the full use of a crippled hand—that is where the ultimate recovery is possible—the member must be systematically used, exercised, and constantly flexed

Fig. 3.—Palmar aspect of left hand of Clarence Baker.

and extended. This gives strength to the fingers and palm; stretches any cicatrix that may have formed, and compels the muscles and their tendons to do their duty.

Having obtained films of the method employed to secure these and other remedial measures, it was arranged to have these six men report to me at the Army Medical Museum, in that I might secure a set of photographs for illustrative purposes. This took place on the seventh of November, 1918, when the same men mentioned above, duly reported and were taken to the photographic rooms for the purpose of posing while using the reinforced tools, forks, and so on. Many photographic exposures were then made, and a very successful series of negatives obtained to illustrate Major Allen's suggestions. A number of the reproductions from the prints from these illustrate the present article.

In that the records may be as full as possible, there are here inserted the names of the above men, and brief notes on each case:

No. 1. John Avelrsa, 37th Division, U. S. Infantry, Italian, age 28 years. Machine gun bullet; center of palm of left hand exhibits the wound of entrance. Received in engagement in Lorraine, August 20, 1918. U. S. medical officer attending. Wound healed. Returned to United States on October 21, 1918.

No. 2. Hazel Asbury, 7th Infantry, American (West Virginian), age 26 years. Piece of shell; center of palm through dorsum; left hand; received at Chateau Thierry, July 26, 1918; wound entirely healed; attended by U. S. medical officer. Returned to United States Oct. 21, 1918.

No. 3. Abert Gilli (colored); 301st Stevedore Regiment; Virginian; aged 20 years. Pinched between two box cars in France, crushed left hand while loading hay on car. Healed. Eight months in hospital. U. S. medical officer attending. Returned to United States Oct. 21, 1918.

No. 4. Clarence Baker, 166th U. S. Infantry, American, aged 23 years. Pistol wound, cal. .45; ball entered outer base of index finger of left hand, passed to base of ring finger, leaving linear scar on palm at base of 3rd metacarpal, finger removed. Wound beautifully healed. U. S. surgeon attending. Received at Motini, France, June 17, 1918.

No. 5. Corporal R. J. Johnson, Co. B, 29th Engineers, aged 24 years, born in Princeton, Mich. Left forearm, middle; explosive machine gun ball. Wound of entrance radial side. Wound of exit, linear cicatrix, 5 inches in length in line with ulna. First German offensive, March 21st, 1918; wounded on March 30th, 1918. U. S. surgeon attending. Returned on transport August 11, 1918. Healed rapidly.

No. 6. Pvt. Allen B. Cremeans, 28th Infantry, Hdqr. Comp., aged 30 years. Native of Duerandotte, Va. Wounded left hand near center; entrance on dorsum; exit on palm. Heavy cicatrix. Grasp feeble. Scrap of high explosive shell, 2 in. depressed cicatrix. Somme front, France, May 29, 1918. U. S. surgeon attending. Healed promptly. Base Hospital treatment. Finally returned on transport, Oct. 21, 1918.

All that Major Allen requires to carry out what he aims to accomplish is a supply of ordinary gelatine, and a requisite amount of the ordinary modeling composition used by dentists in their plate work, or by artists to meet various ends in their work. This material comes in small boxes at half a dollar a box, which latter contains some five or six cakes. These are three or four inches square, a quarter of an inch in thickness and of a rather deep Indian red color. Those who have ever used this composition know that it possesses the very valuable property of becoming thoroughly soft and plastic when placed in hot water for a few moments and that without melting or running. Then, when thus softened, if plunged in very cold water—ice-water, if convenient—it at once hardens again and becomes as brittle as some forms of amorphous rock, or perhaps more like terra cotta, or some kinds of glass.

This process may be gone over and over again without any deterioration of the composition, or the minutest loss of its substance. Now a typical case of one of these gunshot wounds is here shown in Figures 1 and 2 of the present article, and this man had practically no use of his left hand at all. He

Fig. 4.—Use of the fork with crippled left hand. Pistol wound, cal. .45. Clarence Baker. (See Fig. 3.)

could not so much as pick up a hammer, to say not a word as to being able to use such a tool. He is right-handed, and before being wounded he used his left hand pretty much in the same way that most people normally do. To drive a nail with a

hammer held in the left hand is by no means an easy feat, though it may be accomplished after long practice. This soldier had had no such training; so, in using his left hand, it would only be in such a manner as he would use it had he not been wounded as he was.

Fig. 5.—Use of the saw by aid of auxiliary handle. Pvt. Abert Gilli.

In other words, through using Major Allen's method, it simply permitted the use of his left hand just as though nothing had happened to it. Had it been, on the other hand, the right member so reenforced, he could have used it just as well as though it had never been injured—that is, provided he could have held and steadied the nail with his left hand. This description, as thus far given, applies to all other cases of a similar class. With a fork, or a saw, it is obviously different, as the sound hand may or may not be brought into play. The figures to the present article tell nearly the whole story, taken in connection with what has already gone before. To reinforce a hammer and prepare it for use by the wounded hand, all that is demanded is to take a sufficient quantity of the modeling composition to make a mould of the proper proportions and dip it into hot water. By squeezing and modeling it, it soon—in fact, in a moment or two—becomes thoroughly plastic. In this condition it is made to surround the handle of the tool where the user ordinarily grasps it for use. (Figure 2). Next, his wounded hand seizes this mass of soft compound and presses the parts into it—that is the palm and fingers—until they are comfortably closed and the maximum amount of the wounded member is brought into play, in so far as its grasping capacity is concerned. The tool is then released, and the handle, with the mass upon it, is promptly immersed in ice cold water, or any water that is good and cold. This sets the mould; the patient at once discovers that he can readily pick up a nail with his sound hand and drive it with the one in which he holds the reenforced tool.

As the hand improves and the grasp becomes closer and stronger, the form of the moulded auxillary handle can be readily altered by the patient himself, for all that is required is to dip it in hot water, and then, without detaching it from the tool handle, squeeze it with the wounded hand until a well-fitting, comfortable handle is moulded, and then fix it by immersion in cold water. In order to exercise the wounded hand when not used, Major Allen has introduced another contrivance. This consists of preparing a gelatine mould of the clasped hand by closing the wounded member upon a mass of gelatine of the proper size and consistency, and then setting the form aside for a while. Such a mould may be carried about in the hand without attracting much attention, or causing much inconvenience, while through the constant squeezing and releasing of such an object of proper resilient nature, the entire hand will be receiving the very kind of exercises required to restore—or help restore it to usefulness and health, as far as the ultimate result will permit. It is remarkable how satisfactorily, and often how rapidly, a wounded hand will improve under such treatment.

In Figures 1 and 2 we have a chisel armed with a mould in the manner described above. The hold of this tool in the wounded left hand is well shown in Figure 1. There, as held, the hand presents its maximum capacity for grasping, so that to hold the handle of the chisel would be out of the question, unless the composition mould was fitted on as shown in Figure 2, which is the same as the one shown in Figure 1. As thus equipped, this man could use his wounded hand with a chisel almost as well as though the injury had never occurred.

The dark area on the handle of the hammer in Figure 1 is nothing more than the thin remains of a composition mould that was attached over the area indicated for another case. It has nothing to do with the treatment of the patient shown in that cut, where the use of the chisel alone is demonstrated.

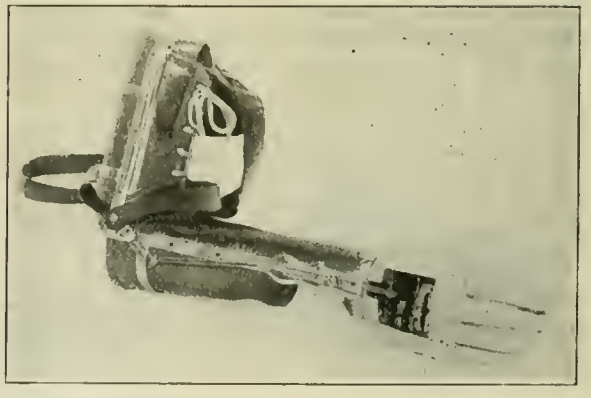

Fig. 6.—Modern artificial arm with detachable hand. Device to use the fingers. For amputations in the upper third of forearm.

Frequently, these wounded hands are quite incapable of holding either the knife or fork when partaking of a meal, and at other times. Here is where Major Allen's reconstructed handle comes in with especial aptness. Our case of Private Clarence

Baker, cited in the list of cases above, admirably illustrates the value of the plan to patients so crippled. The power of grasping with his left hand is practically nil (Figure 3) as his wound was a very vicious one. However, the injury healed well, and doubtless, in time, a large part of the use of the member will be practically restored. But, be it remembered, during these long months of waiting, the power to feed himself is very markedly deficient. It was most gratifying and truly remarkable to note the improvement in his case as soon as the handle of the fork had been adjusted to his wounded and practically useless left hand (Figure 4). While a little clumsy at first, it only required a few trials when he appeared to use his knife and the aforesaid fork quite as well and as efficiently as though the hand were a perfectly sound one. Without the moulded handle, Baker's left hand could barely pick the fork up from off the table, and was absolutely powerless to hold it, let alone use it. His delight in being able to do what he could so efficiently do in such a necessary matter can be readily imagined. By the use of the "gelatine exerciser" and the moulded handles to the tools of his trade, the wounded hand of this man will be restored, as far as it can be restored, to its normal condition prior

Fig. 7.—Same arm as shown in Fig. 6, with composition moulded on to form a false hand to hold a fork. By the usual process this may be removed and a similar one fitted to hold any other tool or instrument.

to the injury, much more rapidly than it otherwise would, while at the same time he will enjoy very good use of it during this period.

In Figure 5 we have another good case wherein the handle of a saw has had fitted to it such a mould as I have described above. To some extent, this man could use the saw even with his left hand and arm, for I observed him do so as depicted in the cut. Had the right hand been the wounded member, and its recovery proceeded as far as shown in the illustration for the left one, the use of the saw would have been almost perfect, through the application of Major Allen's method of reconstruction.

These few selected cases will sufficiently illustrate what it has been my pleasure to set forth in this article. The suggestion—or the method, as it is more than a suggestion—is capable of expansion in not a few other directions. These are likewise of an orthopedic character, and make for definite, modern, and scientific orthopedic results, which not a little of the output of the orthodox part of that branch of surgery distinctly does not do in these days.

One more example of the use of this method, then, and I will leave the subject for others to elaborate and enlarge upon. It is a well known fact to the manufacturers of artificial limbs and to surgeons that the efficiency of such inventions, or contrivances, depends almost entirely upon how perfect the hand has been made, or such devices as may be attached to the wrist, in that certain things may be performed with more or less comfort. For example, a plain hook may be attached there and used to carry a pail of water, or packages, and so on. Such devices have, to a large extent, multiplied since our entry into the present war so that one wearing an artificial arm can now have various devices attached to it at the wrist by means of which he may be an efficient catcher in a baseball game; play croquet, or golf, or tennis, and so on for many other vocations or purposes.

Up to date, these devices or attachments have been very clumsy, as a rule, and only fulfil their purpose in part. For example, we have quite a complicated one here shown in Figure 6. It is designed to use the thumb and fingers, and is detachable. As a matter of fact, it gets out of order altogether too readily and presents other disadvantages.

Now, by using the composition prepared by Major Allen, and carrying out his idea in another direction, we may make a rough model of a hand, and when it is in the plastic condition, it may be made to hold any tool or instrument that the cripple desires to use at the time. In Figure 7 it is shown holding a fork, which is held in a convenient position in the hardened composition. This mould or composition hand may be detached and another screwed on in a moment, to meet what the man desires to perform after his meal is over. Then, too, it is an easy matter, and one that requires but a few minutes, to plunge this "hand" in hot water, remove the fork, insert a lead pencil or a pen, or anything else as for the matter of that, which the cripple desires to use next, dip the composition in ice water, and in a very brief space of time the member is ready for use as desired. An ingenious person may work in all sorts of useful designs, as a single finger that may be used on a typewriter, and for a great many other purposes. In other words, an artificial arm, with a detachable hand may, by this plastic hand attached, be made to be ten times more serviceable than the artificial hands as they are now usually manufactured.

At the request of the Commandant, I have placed on exhibition at the Army Medical Museum at Washington quite a complete set of these plastic hands of Major Allen's, as well as photographs exhibiting their several uses. They have created not a little interest, and, I may say, favorable criticism on the part of those orthopedists who have studied them. In other words, it looks very much like a very valuable device and method which has come to stay.

Banquet to Professor Pereira.—As a result of his labors in the direction of rural hygiene in Brazil Professor Miguel Pereira was tendered a banquet last Spring at Rio de Janeiro by his medical colleagues. The statement that Brazil is a vast hospital has passed almost into an axiom. It is claimed that 80 per cent. of Brazilians die without medical attendance. The activities of the honored guest have done much to remedy these conditions by preventive measures.—*Brazil-Médico.*

AN ORIGINAL DEVICE FOR THE CONTROL OF HEMORRHAGE FROM THE LARGE SINUSES OF THE BRAIN BY INVULSION OF THE OUTER WALL INTO THE LUMEN.

WITH REPORT OF A SUCCESFUL OPERATION FOR CEREBELLAR ABSCESS BY OBLITERATION OF THE LATERAL SINUS AND EXPLORATION AND DRAINAGE THROUGH ITS INNER WALL AND ANTERIOR SURFACE OF CEREBELLUM.*

By WELLS P. EAGLETON, M.D.

MAJOR M. C., U. S. A.

NEWARK, N. J.

THE physiological and mechanical factors and clinical experience require that the exploration of a cerebellar abscess originating from infection of the petrous pyramid should be through a dural opening, situated as far forward as possible, in order to lessen the cerebral herniation and permit of adequate inspection and evacuation.

Surgical Anatomy of the Lateral Sinus.—The position of the lateral sinus at the junction of the anterior and lateral surface of the cerebellum limits the area in which exploration may be conducted, and if the lateral sinus is "forward lying" it may prevent exploration without destruction of the labyrinth and injury to the facial nerve.

The blood pressure in the descending portion of the lateral sinus, normally but a few mm. of mercury, is negative during each inspiration; the collapse of the sinus with each inspiration being frequently witnessed during its operative exposure. The volume of blood, although under low pressure, is large. This low or negative pressure enables hemorrhage following injury to the sinus wall to be controlled by closure of the gap, the lumen of the sinus remaining permeable. The gloved finger, a small piece of cotton, or the "postage-stamp method"—in which a piece of fascia lata is placed over the vent, the fascia adhering to the injured sinus—controls the hemorrhage without stopping the current of blood within its lumen.

However, it requires considerable force to control hemorrhage from the sinus by invulsion of its outer wall by compression, because of the large volume of blood and the triangular shape of the sinus.

While the disturbance to the return circulation by obliteration of the lateral sinus is very slight,[1,2] the mechanical difficulties of ligation of a pervious lateral sinus are so great that it has been previously practised in but two recorded instances.[3,4]

Cross-section.—The lumen of the descending portion of the lateral sinus opposite the middle ear is an irregular oval, with its greatest convexity outward, the sinus tunneling, as it were, between the layers of the dura; the inner wall of the sinus is flush with the contiguous dura over the cerebellum, while the outer wall of the sinus projects considerably beyond the outer dural surface. Obliteration of the sinus by encircling ligation is difficult, because in its horizontal diameter the sinus presents *two* fixed points of dural surface that cannot be approximated.[5]

Reaching the knee the sinus becomes distinctly pear-shaped, with inner wall still flush with the contiguous dural surfaces of the cerebellum and cerebrum. The superior petrosal sinus enters at an oblique angle, emptying, as it were, into the *inner* wall at its posterior margin. This is of surgical

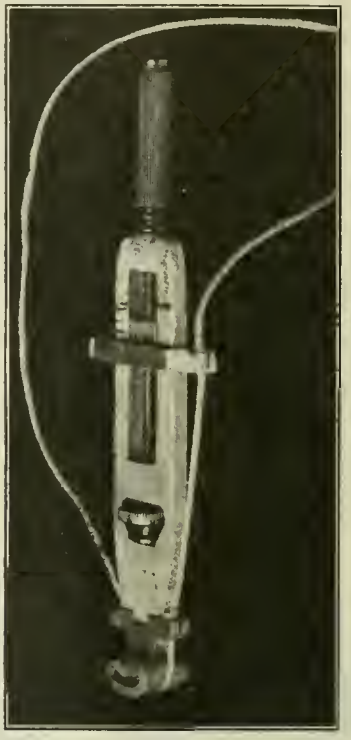

FIG. 1.—Sinus obliterator; carrier showing knotted suture in slots on one side and obturator attached.

importance. After passing the knee the horizontal portion of the lateral sinus assumes a triangular shape, with *three* fixed points. The dura of the tentorium cerebelli being interposed between the superior and inferior dural attachments.[6] Because of the three fixed points of dural attachment it is difficult to obliterate completely a large transverse sinus by an encircling ligature, the tightening of the ligature tearing the dural attachments, with resulting hemorrhage.

However, in both the transverse and descending portion of the sinus it is possible to invulse the outer wall into the cavity of the sinus, thus *completely obliterating it.*

Obliteration of the Lateral Sinus Preparatory to

FIG. 2. Obturator of the sinus obliterator, detached.

Incision.—The appliance holds the two ends of suture apart so as not to compress the fixed dural attachments, while the descent of a metal obturator causes an invulsion of the outer wall of the sinus into its cavity, obliterating its lumen.

*Presented before the annual meeting of the American Rhinological, Laryngological and Otological Society, Atlantic City, June, 1918.

Technique of the Application of the Suture.—A small opening is made in the dura, on each side of the sinus, using a triangular dural knife or cystotome. A ligature is passed from one dural opening to the other, using a full curved needle with the point blunted, damage to the cerebral tissue being avoided by hugging the dural surface. One side of the ligature is knotted in its center and the suture placed in the slot of the carrier and of the obturator of the same side. The other side of the ligature is then placed in the opposite slots, and, using the knotted point of the ligature as a fulcrum, is tightened sufficiently to cause slight indentation of the sinus; when the ends of the ligature are tied in a bow knot over the cross-arm of the carrier. Tightening the upper screw of the carrier will cause the descent of the obturator into the sinus, obliterating its cavity. Using an artery clamp, the slots in the soft metal arms of the obturator are then pressed firmly against the suture, holding it in position; the suture above is then loosened, and removed from the slots of the carrier, and the obturator is liberated from the carrier by unscrewing the lower screw. (The suture may now be tied over the obturator.) If the ligation is to be made above the knee it will be necessary, in addition, to perforate the tentorium cerebelli with the needle.

The upper portion having been obliterated, and all downward current of blood stopped, the lower portion of the sinus is easily ligated, as the sinus walls are here much nearer; or if the bony exposure is low enough the lower portion of the sinus may be obliterated by the pressure of a tampon against its firm bony wall. Between the two ligatures the sinus can be incised. In the case reported below in which I used the appliance the incision of the sinus was absolutely bloodless.

The obliteration of the sinus frees the approach to the anterior triangle of the cerebellar fossa, making possible the enlargement of the dural incision in front of the sinus. Through the enlarged triangle the whole of the inner side of the dura over the anterior surface of the cerebellum can be inspected and the region of the adjacent cerebellum (the most frequent site of cerebellar abscess) exposed.

Case S. B. History by Dr. J. W. Hurff. Influenza followed by acute otitis media in right ear. Mastoid operation performed, neither dura nor sinus being exposed. Three weeks later wound had practically healed; no symptoms. Five weeks after operation, dull boring pains commenced behind right eye and in right frontal region. Paroxysm of pain was followed by vomiting, and for two weeks there was headache of varying intensity on the right side and frequent projectile vomiting which was influenced by the position of the patient, who could take food when lying on the right side but would vomit upon turning on his back.

Two weeks later the patient was much improved and could walk about the room, although when he first attempted to walk he staggered and had a tendency to fall to the right. No strength in right arm; used left. Became dizzy on sudden change of position. Headache subsequently increased in severity, right sided weakness became more marked, and the patient became slightly confused mentally. Examination showed the mastoid scar to be healed. No discharge from ear. Patient could hear with right ear. Cold caloric in right ear produced nystagmus, but not nearly so marked as that produced in left; complained of blurred and double vision. Ophthalmoscopic examination revealed congestion and slight edema of both discs and fixation nystagmus. Mentality dull; no aphasia. Pulse 60; respiration irregular, bordering on Cheyne-Stokes. Cerebrospinal fluid clear under pressure.

Movements of pronation and supination were overdone. Asynergia more marked on the right side, as shown in his inability to coordinate the various muscles and joints. Asked to put his right hand back of his head, his arm would apparently wobble in every direction until he got it in place, or he would raise the right hand with the left. The right hand was much weaker than the left.

The old mastoid cavity was therefore reopened and the sinus exposed, but no trace of infection was found. Three days later, May 12, 1918, a cerebellar operation was performed (W. P. E.), hemorrhage being controlled by Von Hayden's instruments. The whole cerebellar fossa was exposed on the right side, and the posterior surface of the petrous pyramid removed as far as the internal auditory meatus. Difficulty was experienced in locating the sinus on account of granulations; but it was found by approaching from behind forward. A blunt needle threaded with heavy silk was passed just below the sinus knee encircling the dura from behind forward and out on the anterior wall of the cerebellar fossa. On first passing it undoubtedly perforated the sinus. The sinus was obliterated by the instrument above at the knee, and was again tied with an encircling ligature as low down toward the bulb as possible. Between the ligatures the external wall of the sinus was then opened without loss of blood, and the incision was continued through the inner wall to the cerebellum. This incision was afterwards enlarged, the opening into the cerebellar fossa being directly at the angle of the anterior and external surfaces. There was no prolapse of the brain. Exploration with searcher at distance of 3 cm. located the abscess with capsule, pus flowing freely. On introduction of Whiting's instrument (encephaloscope), pus again flowed. The capsule could be felt at the bottom of the encephaloscope, and pressure expressed more pus. The abscess cavity was thoroughly cleansed and wiped out. There was slight herniation of the brain. A rubber tissue drain was inserted and the wound closed. The obliterating obturator was removed on the tenth day. Uninterrupted recovery.

FALSE TEETH AS A CAUSE OF CANCER.

By C. Everett Field, M.D.,

New York,

Director, Radium Institute.

The plates used for supporting false teeth, when imperfectly fitted, are proving such a prolific source of cancer that a note of warning should be sounded to the general public. The medical and dental professions will do well in co-operating to take prompt action whenever there are indications of chronic irritation of the gums from which teeth have been extracted. There have come under my observation as director of the Radium Institute of New York City many instances in which faulty artificial dentures have caused the development of malignant growths along the line of the maxillary processes. Ill-

fitting sets of false teeth and bridge work have probably been responsible for many deaths from cancer, and I have no doubt that in the early stages of the dental art when more or less clumsy appliances were in vogue the list of fatalities traceable to such causative features must have been large indeed.

The mouth with its tender membranes is peculiarly subject to injuries which are difficult to heal. If there be a predisposition toward cancer, it is likely that it will crop out in any region where the soil has been suitably prepared to foster the growth of malignant cells.

Where a set of teeth fit imperfectly, the constant abrasion on the gums causes, at first, the development of an area of congested tissue. In time, this formation degenerates into an ulcerated state, which, although innocent enough in the beginning may soon exhibit a rapid malignant transformation. The changes from a healthy structure of the gums to that of cancer moves on so insidiously in the early stages that frequently the condition when recognized is difficult to combat. Many years ago, the writer, recognizing the importance of oral or mouth hygiene, wrote a paper calling attention to the mouth as an organ which maintained all the requirements of a laboratory for the cultivation therein of disease-producing bacteria. It, therefore, should be maintained at all times in a healthy state.

The basis for this report is a minute analysis of a series of 87 clinical cases coming under the observation of the author during the past three years. I have also made an exhaustive study of the available literature on the subject. Recognizing the large number of cases of cancer that seemed to trace a tributary cause to artificial dentures, I determined to give more careful attention to the early history of such cases as might thereafter present themselves. The summary was more important than I had anticipated, indeed, the findings were so conclusive as to be startling.

Of a classified series of 157 cases presenting malignant processes involving either the superior or inferior maxillae, 87 presented a clinical history that showed the initial ulceration or nodule to be in close proximity to an artificial denture of which the patient offered complaint. Examination of the dental appliance in many cases presented evidences of castings and fittings that were a disgrace to the dental art. Many of the plates had originally been well fitted but natural changes affecting the alveolar processes made the dentures of poor service. For this feature, of course, the dentist should not be censured.

Many of the plates, however, in the mouths of the poorer classes, we found had been made and placed as promptly as two or three days after the extraction of numerous teeth. Such treatment should constitute malpractice. It is well to note that our records showed 58 of the cases had exercised little attempt at oral hygiene and allowed existing plates to remain in filthy condition. Many of these had stumps of decayed teeth still in the alveolar sockets in varying degrees of putrefaction.

Fifty-two were males and 35 female patients. Of the men, 28 were classed as heavy smokers. The average age of this classification was 58 years. We have entered in our records only cases whose history we were able to follow to date.

Of the 87 cases recorded, 19 showed original development adjacent to bridge work and 68 near plate work, of various types. The malignancy presented in 59 cases in the superior maxilla as against 28 affecting the inferior maxillary region. The tumors were classified as follows: Carcinoma, 65; sarcoma, 9; osteoma, 3; fibroma, 4; chondroma, 4; and melanosarcoma, 2.

It is regrettable to report that a large majority of cases of this type applying to the Institute for treatment present themselves in most advanced stages. Fully 50 per cent. of those who come for radium treatment must be immediately listed as hopeless. An early diagnosis, say within the first three months, would reduce this mortality at least 20 per cent. It is not uncommon to accept such patients with a report of 12 to 18 months of delay. Some of these have had simple measures of treatment but few have even applied for surgical help.

Where operative measures have been resorted to and recurrence results, the growth frequently becomes exceedingly active and any period of delay at such a time soon makes the case hopeless for radium.

Treatment.—The most important factor of management of every case is to decide what measure of success we may anticipate with surgery and promptly institute such treatment. In operation, the area should be attacked widely for thorough removal. Post-operative radiation, with adequate amounts of radium, is of prime importance. As a rule, the first radium application should be made within ten days following the operation and be followed by three or four subsequent radiations, at five-day intervals. Such a treatment we would class as ideal in every case where operation is possible.

Unfortunately the majority of the cases coming to us are classed as inoperable. We find, however, that under radium therapy, about 8 per cent. of such cases are improved to the point where operative procedures may be favored. As a net result of the 87 cases here enumerated, radium accords a clinical cure in about 18 per cent. By clinical cure I mean a complete retrogression of the mass and its failure to recur for periods running from 32 months down to 6 months. Marked temporary improvement followed radiation in 65 per cent. of these patients. While this is not as promising as we would wish, we believe that no other form of treatment could have attained such results.

So far as dosage is concerned the cases were of such varied types that a full report would be too voluminous for this paper which is simply a preliminary report. The average dosage in the 17 patients permanently improved, however, amounted to 3600 milligram hours, with individual treatments, averaging 180 milligrams of radium element. The favored screenage was with sufficient brass or platinum and metal-free rubber to assure pure gamma radiation. Burns from the use of radium, although not to be feared, were rarely seen in this method of treatment. Cross-

fire application was encouraged at every possible opportunity.

I wish again to lay importance on the finding that the inoperable carcinoma case under radium treatment not infrequently becomes operable. We have on record two patients who owe their lives to-day to the fact that radium successfully controlled the growth and reduced it to a point where a successful operation could be performed. Post-operative radiation of cases then followed. Both cases had been classed as entirely hopeless and inoperable. At the present date, after 2 years, both have remained normal.

Radium offers to the truly hopeless and inoperable cancer case the one relief possible and seemingly it gives such aid in every instance. Commonly we see much of the pain lessened, the discharges improved, the odor checked to a degree and the patient comforted. While improved technique and a better understanding of dosage may be increasing somewhat our success in the treatment of cancer, we feel that far better results can be secured by urging the necessity of a more prompt recognition of the early signs of malignancy.

Realizing the value and importance of hearty co-operation on the part of the dental surgeon with the family physician in facilitating prompt diagnosis and treatment, I am requesting all dental practitioners to give this subject watchful attention. I feel that the average person wearing artificial dentures does not report to the dentist as frequently as he should, following the introduction of new bridge work, plates, etc. At certain periods the changes in the structure, both bone and tissue, are very considerable and that which would be considered a perfectly adapted denture to-day may three months hence be a source of continual irritation. Perhaps an equally serious pathological condition to be considered is the chronic pericemental hyperemias and untreated pyorrhea alveolaris cases. The latter is an exceedingly common state which is quite often associated with cancer of the superior and inferior maxillary regions.

Let it be emphasized, as strongly as possible, that any chronic irritation serves as a predisposing factor at least in causing cancer. Let it also be emphasized that cancer is at first a local disease, which for a time is held within its own confines. As such it is curable by prompt and thorough removal. Let it still further be emphasized that the sole reason why cancer is at present so seldom cured is because it is rarely recognized in its primary state and promptly accorded treatment.

The lamentable statistics that constantly confront us will be wonderfully improved by the extension of such information as will educate the laity to the degree whereby they will not be ignorant of the known facts about cancer. The benefits of such knowledge should be widely disseminated by means of the physician, dentist, nurse, teachers and settlement workers throughout the land. In this way, and by such means only, can we hope to greatly improve this important phase of the cancer problem.

205 West Seventieth Street

SLEEP AS MENTIONED BY RABELAIS.

By DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO, CAL.

Almost the first question a physician asks a patient is "How did you sleep last night?" so important is this condition in a return to health, and yet natural sleep is hardly ever mentioned in treatises on the practice of medicine, or, if so, is quite casually treated, and the physiologists are almost as indifferent. The physician Rabelais was immensely interested in sleep, and has left several remarks on it which will live as long as the French language, and the French language is likely to exist for yet several hundred years, in perfect accord with the virility of the French people.

Rabelais' Belief That the Soul Left the Body During Sleep.—In a discussion by Pantagruel regarding the validity of dreams in foretelling the future, the soul is compared to a nurse in charge of an infant. He goes on to say that:

When an infant that is well cared for, amply nourished and sufficiently supplied with milk, sleeps profoundly, its nurse is at liberty to leave it, and to do as she pleases, as her presence about the cradle is not necessary. In the same manner when the body sleeps and digestion is completed, our soul rejoices and flies away to revisit its native land, which is heaven,[1] and while there gathers impressions, which, as dreams, give a true indication of coming events.

Nourishment and Sleep the Prominent Features of Infant Life.—The existence in utero is supposed by some to be a perpetual sleep. The new-born babe sleeps frequently and profoundly; and may be completely dressed or undressed without interrupting its slumber.

Rabelais, who never forgot to feed either his infants or adults, says that Gargantua, from his third to his fifth year, was nourished and instructed in all suitable discipline by commandment of his father, and passed his time in the very same way as the other little children of the country, that is to say, in drinking, eating, and sleeping, in eating, sleeping, and drinking, and in sleeping, drinking, and eating.[2] These vegetative occupations together with commendable enterprise in playing and especially in playing with a dog, completely filled the days of his child existence.

An Adoleseent's Attitude Toward Sleep.—Rabelais gives a couple of pictures of how the youthful Gargantua, still under the guidance of tutors and before going to the university, passed his time. After muttering a number of graces, he drank from a wine cup so full that it overflowed its borders, and cleaned his teeth on a knuckle of ham. The company then retired to the gaming table, where, after having played, littered, frittered, and sifted away their time, they felt it opportune to do a little more drinking, then, immediately after banqueting, they stretched themselves out on a fine sofa or a beautiful large bed to sleep two or three hours without thinking an evil thought or saying an ill-natured word about anyone. On awaking, the youthful Gargantua shook his ears a little and drank better than ever.

Ponocrates, Gargantua's new tutor, who was watching the youngster with a view to turning his

activities in a better direction, remonstrated with him, telling him that it was not at all commendable to drink so soon after sleeping. Gargantua, who regarded every thirst as a fitting opportunity to enjoy a glass of wine, answered that he was acting according to the real life of the Fathers of the Church, and that it was natural for him to sleep with a salt mouth, which was every bit as advantageous, as far as thirst was concerned, as eating so much salt ham.

The above meal was evidently the noon meal, and the delightful repose followed hard upon it. After telling how the rest of the afternoon was passed, he and his noble companions came to supper, after which games were played. Then they went to see the girls thereabout, and enjoyed little banquets among them, and collations and after-collations, after which they slept without removing their clothes, and remained so until eight the next morning.[3] Just like modern youngsters they could not be driven to bed at a decent hour with a stick, nor could they be roused out of it betimes with an alarm clock.

This, it appears, was Gargantua's training as preparing him for the government of a great kingdom. When Ponocrates took the young prince in charge, he put him through an entirely different course of training both mental and physical, and Rabelais, true to his clerical discipline, does not omit the religious exercises which immediately preceded his retirement for the night.[4]

After reading these two descriptions, the one a satire and the other evidently a straightforward educational plan, one cannot remain in doubt as to the good will Rabelais had toward the world. It is unjust to designate him as an out-and-out mocker, and destructive critic.

Panurge's Idea of the Valuelessness of Dreams in Foretelling the Future When Sleeping on an Empty Stomach.—Panurge, on improving in his financial affairs, was mightily exercised as to whether he should marry, and if he should marry whether his wife, seeing he was entering into the frosty years, would prove true to him. In order to resolve these important questions he determined to resort to the interpretation of dreams, and in order to obtain good dreams the quality of his sleep was of importance. He told Pantagruel, whom he consulted on this point, that if he did not sup well and abundantly, his sleep would be troubled and his dreams would be as hollow and valueless as his belly was empty.

Pantagruel, possibly remembering the Scriptural admonition that "the abundance of the rich will not suffer him to sleep," insisted that the evening meal should be light, particularly when the dreamer was corpulent and of a full habit, as in Panurge's case.[5]

This is not the first time that Panurge is mentioned as sleeping well on a full stomach. When he first entered Pantagruel's service he was as thin as a lath, had a nose like a razor handle, and was famishing from hunger. At Pantagruel's invitation he fed amply that evening, and went to bed like a capon. He slept well till noon of the following day, and on awaking took three steps and a jump from the bed to the dining table.[6]

The Somnolent Effect of Religious Exercises.—Friar John, as a monk, was well aware of the somnolent effect of religious exercises, and of sacred literature.

When the youthful Gargantua returned from his student life in Paris to take part in the great Picrocholean war, he and his companions got supper, after which they consulted what they should do. It was determined that about midnight they would sally forth in skirmishing order to ascertain the disposition of the enemy. In the meantime they went to bed, and Friar John and Gargantua slept together. The young prince was restless and tossed from side to side, and could not sleep. Friar John said, "I never sleep well or at my ease except when I hear a sermon, or am at prayers. Let us begin, you and I, the seven penitential psalms, and see if we shall not soon be asleep." They began on the first psalm, but before they had reached the first verse of the *Beati quorum*, that is of the second penitential psalm, they were sound asleep and they slept till midnight, when Friar John awoke, as from habit, being habituated to arise at this time for early matins.[7]

The first words of the seven penitential Psalms are:

I. O Lord, rebuke me not in thine anger.—Psalm VI.

II. Blessed is he whose transgression is forgiven.—Psalm XXXII.

III. Lord, rebuke me not in thy wrath.—Psalm XXXVIII.

IV. Have mercy upon me, O God, according to thy loving kindness.—Psalm LI.

V. Hear my prayer, O Lord, and let me cry unto thee.—Psalm CII.

VI. Out of the depths have I cried to thee, O Lord.—Psalm CXXX.

VII. Hear my prayer, O Lord, give ear to my supplications.—Psalm CXLIII.

The somnolent effect of these when recited in the full-voweled Latin tongue may be imagined. Friar John as a monk, and Gargantua as having been trained in his youth by clerkly tutors, would both be able to recite these psalms without mental effort, and in perfect rhythm and accord.

As a young man Gargantua had to undertake some of the severer tasks of government. A previously referred to war had broken out between a bad neighbor called Picrochole, and the good old king Grandgousier. The heir to the throne had to undertake this active fighting, and after the battle he returned home to the palace at daybreak where quite naturally the elderly monarch was found still in bed praying God for the safety and victory of the enterprise. And, seeing them safe and sound, he embraced them lovingly.

Although Grandgousier was in bed he seems to have been alert, for he immediately evinced one of the characteristics of a good political leader. The first welcome over, he inquired instantly for one of his son's missing henchmen, the energetic and warlike monk, John of the Trencherites, who had been taken prisoner by the enemy.[8]

Pantagruel, the son of Gargantua, would rather drowse over a book than attempt to put himself to sleep reciting by heart. The specific occasion for remarking this was a calm at sea, which is a most drowsy time, especially on a sailing vessel. Here

Pantagruel fell asleep, holding in his hand a copy of the Greek author Heliodorus.[9] He undoubtedly had chosen this author intending during the large leisure of an indolent day to be edified. In the same way I knew a most estimable woman, who, on every drowsy Sunday afternoon, would seat herself in a rocking chair with her Bible. Presently the Bible would be in her lap and she would be asleep.

In Rabelais' day the church was a career much more frequently entered than it is to-day. It was an enormous institution with immense revenues, and an infinity of places paying a small salary. Just such places as are loved by those who desire a secure living and an easy life, and yet whose wants are few. A very mediocre education in one of the universities was enough to obtain such a place, and this partly explains the great crowds of poor students who attended these seats of learning. Having secured the church living, the tendency was for the occupant to fall into routine, and to enable one to do this without embarrassment there was published a very popular book of sermons called the "Dormi Secure" or Sleep in Peace. The title meant that the preacher might sleep soundly and not arouse himself in the morning in order to compose his sermon, as sermons suitable for every conceivable occasion were all duly set forth in this convenient book.[10]

Rabelais was a monk, and although the word means "alone," it came, as Chesterton says, to mean a community, and a very close-knit intimate community. People when intimately thrown together for long stretches of time, as in camping parties or on yachts, become disagreeably aware of peculiarities in their neighbors, and Rabelais touchingly refers to snoring.

Carpalim, the swift one, went lightly among the Dipsodes and Giants, whom Pantagruel was besieging, and they did not remark him, so profoundly did they snore and sleep. So successful was he that he reached the place where they kept their artillery and set fire to their munitions, and ran considerable danger to his own life from the rapidity with which the powder blazed up.[11]

In another situation Rabelais mentions a community where the people gained their living by sleeping, and those who could snore the loudest made the most money.[12]

Alcohol As a Soporific.—In his famous enumeration of the five means of restraining carnal concupiscence, Doctor Rondibilis begins with wine. He had hardly got the words will out of his mouth when Friar John broke in with "I can well believe it, for when I am drunk I only want to sleep."[13]

It has been supposed that sleep is produced by a sort of soporific agent generated by our cellular activities while we are awake. The state of being asleep, however, is probably as normal as being awake, and it would be just as logical to suppose that during sleep an exciting agent was generated, which, when enough was produced, aroused the individual to conscious activity.

And what a mysterious event natural awaking is! To paraphrase Ambrose Bierce: What whispers into the ear of our spirit the mysterious awakening word which no human lips ever have spoken, no human memory ever has recalled?[14]

Howell believes that the regulation of the vasomotor system involved in the occurrence of sleep is effected mainly through variations in the cutaneous circulation.[15] This might explain the importance of sleep in the cure of many diseases of the skin involving the vascular system, as for example, eczema. We are accustomed to say that when a patient suffering from acute extensive eczema begins to sleep well his recovery is assured; even chemically induced sleep, as by bromide of potassium, is frequently a great aid in the treatment of such cases.

The most rational view of sleep seems to be that it is a periodic or rhythmical state of repose, which appertains to all cellular life, from the contractile vacuole of the ameba to the heart of man; the heart-beat, indeed, is the most striking example of this rhythmical succession of work and rest. It has been even calculated that the heart works just eight hours out of the twenty-four—that its contraction, its expansion and its period of rest correspond to eight hours of work and sixteen of rest. Many of our functions and our desires are periodic, hunger, for example; and our whole life, in the larger sense, is a period—we are born and after a period we die. The activities set up in the egg, and probably stimulated by fructification, exist for a period varying with the animal and then cease.

DISTRESSING GENERAL AFFECTIONS TRACEABLE TO EYE CONDITIONS.

By J. A. KEARNEY, M.D.,

NEW YORK.

PROFESSOR OF OPHTHALMOLOGY NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

By a process of elimination of the probable causes of distressing general affections, a decision is usually finally obtained. Among the most frequent sources are irritations existing somewhere in the body, toxemias of various origins, and undue loss of nervous energy.

In the studies of elimination, errors of refraction and extrinsic ocular muscle imbalance are very often found to be fruitful sources of undue loss of nervous energy. Roughened and dry palpebral conjunctivæ most frequently produce irritations of consequence, although disturbances of other ocular tissues are held accountable for some conditions. It is surprising to note in some cases the marked reduction or entire loss of symptoms that takes place following the clearing up of a dry and roughened conjunctiva.

Headaches of various characters, malaise, vertigo, chorea, insomnia, melancholia, neurasthenia, flatu-

lent and other dyspepsias, indigestion, and constipation not infrequently disappear when errors of refraction and extrinsic ocular muscle imbalance of a certain type have been rectified by the wearing of suitable lenses.

When symptoms of a troublesome nature exist and the subject is not presbyopic, refraction should always be estimated under the effect of a mydriatic. The amount of error prescribed is the personal equation of the ophthalmologist, and expresses the results of his observations in these cases.

Should an imbalance exist in the extrinsic ocular muscles, an added correction is ordered, especially if the vertical muscles are found to be sufficiently at fault. When the lateral muscles are in imbalance, stated exercises over a certain period of time usually suffice, and only when exercises have been tried and failed to relieve symptoms should prismatic correction be prescribed for these defects. Prismatic additions to lenses for imbalance of lateral muscles act as a crutch and tend only to defeat the real purpose.

Because a patient is wearing glasses is no evidence that the correction is what it should be at the time he seeks relief. By questioning one will frequently find that the glasses he is now wearing were ordered without the use of a mydriatic; and sometimes he is wearing a correction which, although it had been estimated under the effect of a mydriatic, has now been changed by time.

At a time when a patient is reduced in health or is convalescing from disease or a major surgical operation asthenopic symptoms or other distresses the result of errors of refraction are apt to occur, and if he has been wearing glasses the original symptoms may recur which his lenses were prescribed to correct. An examination under a mydriatic is advisable at this time, and glasses containing the present correction will nearly always clear up the complaints when they are due to errors of refraction.

Conclusion.—Errors of refraction and imbalance of the extrinsic ocular muscles and irritations of ocular tissues, when found to exist and when corrected, frequently clear up many vague and distressing general affections.

Medicolegal Notes.

Refusal of Injured Employee to Submit to Operation.—The law seems to be well settled that an injured employee seeking compensation must submit to an operation which will cure him when so advised by his attending physician, when not attended with danger to life or health or extraordinary suffering, and if as a result of such refusal on his part he suffers a permanent impairment, the employer will not be required to compensate him for the resulting permanent impairment. In a proceeding for compensation for an injury consisting of a "twist and laceration of the index finger of the right hand," there was evidence and the Industrial Board found that at the time of the injury the attending surgeon employed by the employer at first advised the amputation of the finger. The employee remonstrated and insisted that the finger should be saved if possible, and, in response to this objection, the attending physician advised that he had saved fingers as badly injured as that of the plaintiff, and it was agreed to make an effort to save the finger. It was accordingly treated for some time in an endeavor to save it. Infection developed which involved practically the whole of the right hand, and made necessary the amputation of the index finger, which was amputated at the middle joint. The board found that the infection developed because of the delay in the amputation; that the plaintiff's refusal to accept the amputation at the time of the injury was made in good faith, with a view of saving the finger if possible; that his refusal was not wilful, stubborn, or without reason. On appeal it was held that the plaintiff's insistence that his finger be saved if possible, when taken with the statement made by the surgeon, was not such unreasonable or wilful misconduct as would prejudice the allowance of additional compensation.—Enterprise Fence & Foundry Co. v. Majors, Indiana Appellate Court, 121 N. E. 6.

In another case before the same court claim was made for death caused by strangulation of the intestines resulting from hernia. An award was made by the board, which was contested, one of the grounds being refusal to submit to an operation. There was conflict in the testimony on this branch of the case. Some of it, at least, tended to show that the operation contemplated was a dangerous one; that, if it was requested, the request came too late, and at a time when the condition of the deceased was such that recovery therefrom would have been doubtful. Whether a refusal to permit the operation under such circumstances was such misconduct on the part of the deceased and those acting for him as to deprive his dependents of the benefits of the Compensation Act under the authorities, was open to more than one inference by reasonable men, and hence was a question of fact which, when determined by the Industrial Board, could not be disturbed by the appellate tribunal.—Vonnegut Hardware Co. v. Rose, Indiana Appellate Court, 120 N. E. 609.

Subjective Symptoms—Speculative Testimony.—In an action for personal injuries, where the only question was as to the relation between the injuries and the subsequent condition of the injured member, answers to questions to medical witnesses as to the cause of such condition were held proper, and not an invasion of the province of the jury. Evidence of subjective symptoms given by a physician who has not treated the injured person, but has made an examination to enable him to testify as to his condition, was held incompetent; but where there was no contention or proof to the contrary to such testimony, the evidence was but cumulative, and not of sufficient importance to justify a reversal.

Evidence by a physician and surgeon, in reply to a question as to what, if any additional treatment could be given to relieve and cure an injury, that amputation might or might not relieve it, was held to be purely speculative and should have been sricken out on motion. But it was held not prejudicial to the defendant where another physician testified without objection that the only thing that could be done to relieve the condition of the leg was to sever the leg and that would cause the loss of the use of the limb, which in turn would necessitate its amputation, and the defendant made use of this testimony to support the argument that it was the plaintiff's duty to have his leg amputated and thus reduce the damages.—Alpe v. Superior Coal Co., 208 Ill. App. 67.

Charges for Services.—The Louisiana Supreme Court holds that the testimony of a physician and surgeon, to the effect that he was employed by the mother of his patient, a married woman, rather than by the patient or her husband, and rendered valuable services, for which he considered the mother able to pay, but doubted the ability of the husband to do so, was strongly corroborated by the circumstance that the patient, having succeeded as sole heir to the estate of her mother, heard the testimony and did not take the stand to question its verity. It is a matter of common information that physicians and surgeons do not regulate their charges for professional services by any fixed standard of pecuniary value, but, to a certain extent, upon the basis of the ability of the patient to pay, and, on that basis, more frequently than otherwise, perhaps, are but poorly compensated. Where such services are shown to have been of the highest value, in so far as the life and welfare of the patient were concerned, and the charge was neither unreasonable nor inconsiderate, as compared with the financial ability of the employer, the court considered it should be allowed.—Succession of Levitan, (La.) 79 So. 829.

Military Medicine.

ETIOLOGY OF BENT BACK IN SOLDIERS.

MANY of the physical conditions of soldiers, some of them apparently serious, have come to be regarded as hysterical, and when suitable measures are employed in treatment by skilled neurologists their cure sometimes appears to be a ridiculously easy matter. Major A. F. Hurst, R. A. M. C., of Guy's Hospital, London, has been a pioneer both in diagnosing hysterical conditions simulating physical affections and in successfully treating the same. The Seale Hayne Military Hospital was opened on April 15, 1918, for the treatment of soldiers suffering from war neuroses. It is under the direction of Major Hurst. In conjunction with his colleagues he is publishing the "Seale Hayne Neurological Studies." In the second issue of the publication Hurst has contributed a paper on the bent back of soldiers in which he shows that most frequently this is an hysterical manifestation and is easily amenable to appropriate treatment. He points out that the soldier walking slowly and painfully with the aid of two sticks, bending far forward, his arms and legs often shaking with the effort, for all the world like the stage octogenarian, is becoming a more and more common sight.

A considerable amount of experience of this condition since the first case at Lemnos in November, 1915, convinced Hurst that the bent back of soldiers, however variable its etiology, is constant, being always hysterical in nature and consequently always curable by psychotherapy. The most common cause is a blow in the back, due either to the explosion of a shell hurling a man against the side of a trench or causing the parapet to fall on him, or to some accident which might equally well have occurred in civil life. Occasionally an actual wound is present, but this is always superficial, the spine itself having escaped. A history of muscular rheumatism is obtained almost as frequently, pain in the back having followed exposure to cold and damp generally in the trenches, but occasionally at the base or even in home camps. In the large majority of cases an uncomplicated hyphosis is present; in some cases there is lordosis or skoliosis, and occasionally both hyphosis and skoliosis are found.

Malignant Grippe in the Army.—Krafft describes an epidemic of influenza as it attacked a body of troops at Villeret in July, 1918. The latter numbered 500 and had arrived on June 26 to undergo some intensive training. On July 1, after but little drilling, men came to the ambulatory for slight ailments. On the following day 146 of the men sought aid, on the third day nearly twice that number, and on the 4th of the month 320 soldiers were in the infirmary with grippe. The symptoms showed remarkable constancy and the cases ran a mild course. As early even as July 5, 200 men returned to the ranks cured. In the next two days there were 100 more admissions and on July 7 there were still 200 cases in the infirmary. For the first seven days the disease remained mild. But on the 8th there was a notable and quite unmotivated change for the worse. The new victims were very ill and took to their beds at once, although during the mild period not a single soldier had gone to bed as an indispensable act. Instead of subsiding at the end of one or two days the disease persisted with new symptoms, as flushed face. It was no longer the grippe of the textbooks and clinics but a something which was variously termed "malignant," "asthenic," "asphyctic," "congestive," or "violette," from the suffusion of the face. From July 8 to August 2 this type raged. Up to the close of the first period there had been six deaths, but the first days of the grave form saw 15 men die. No further figures are given, but the plague extended to the civilians of the vicinity and destroyed many. The mild type presented a trocheobronchitis with an infantile migratory type of bronchopneumonia. The parenchyma of the lungs was largely spared. Despite the sharpness of the symptoms the men, as stated, were not very ill. After July 7 the picture changed. There was a congestion of the skin and mucosae. The whole surface was involved in the violaceous tint—the color of drowning by submersion. The lips and finger nails were cyanotic. The men were extremely weak and had much pain—headache, myalgia, eyeball ache, sore throat, pains in the chest, etc. They were hardly able to speak or swallow. The whole respiratory tree burned, the larynx being worst. The nose bled as a rule. There was a dry cough and the breath had a mouse-like odor. Fever was high and pulse rapid. There were evidences of extreme congestion of the lungs, which seemed "paralyzed." The patients remained in this condition from one to three weeks. Recoveries were seen in both non-pneumonic and pneumonic cases, chiefly the former. In the first type the symptoms were those of extreme congestion with at most a few small foci of bronchopneumonia. In the second type there were physical signs of massive lobar pneumonia or bronchopneumonia. Strange to relate, a clean cut, typical pneumonia was a good prognostic of recovery. Forecasts of death were a deepening of cyanosis and progressive dyspneal, all deaths taking place from asphysia. The author does not mention the fulminating cases of asphxiating influenza, so common in many epidemics. The blood was always thick and much hemolyzed and the urine always highly albuminous. Slight hemoptysis was usually connected with a focus of bronchopneumonia. Rusty sputum was not seen. Autopsy showed great variation as to the degree of bronchopneumonia from the volume of a nut to an entire lobe. There was never enough to explain the asphyxia which was due to a general engorgement. Under treatment the author lays great stress on venesection as the only means of reducing the congestion of the lungs. On account of low blood pressure infusion of saline solution is necessary. Men were bled as much as a quart. Neosalvarsan was used so freely that 164 separate injections were given. Despite this usage the author seems to have no great opinion of its efficacy. Aspirin, quinine, and caffeine used together were of much value. Camphor, however, proved to be the remedy of choice in the form of

injections of camphorated oil. Adrenalin was rather a disappointment and the colloidal metals absolutely inert. Alcohol was given only at the outset of the severe type. Of the 500 soldiers, not all of whom suffered, 6 per cent were killed—a high death rate for the military.—*Revue Médicale de la Suisse Romande*, December, 1918.

Losses in United States Forces.—Figures have now been compiled showing the total losses in our forces both here and abroad. During the war the total number of deaths from disease in the United States Army in this country was 32,165. Those killed in action abroad number 30,498, and those dying of wounds 12,899. There were in the American Expeditionary forces 2,626 deaths due to accident, while 18,927 died of disease abroad. Deaths in the Marine Corps numbered 2,129, and 738 were lost at sea. This makes a total loss of 99,976, including both officers and men.

Blinded in the War.—According to Major William Shoemaker, who was in charge of the eye departments of all the American hospitals in England, and has recently returned to his home in Philadelphia, the number of American soldiers blinded in the war is surprisingly small, there being not more than one hundred American soldiers who lost their sight abroad. Lieut.-Col. Allen Greenwood, who arrived in New York on January 25, said that of 110 cases of blindness which had been treated in Paris, 76 had returned to the United States. Lieut.-Col. James Bordley, in charge of the reeducation of blinded soldiers, sailors, and marines, at Evergreen Hospital, Baltimore, states that there are in that institution 123 men, and of this number 55 are totally blind.

Less Illness in Army Abroad.—Hospital reports from the Expeditionary Forces show that during the month of January the total number of sick and wounded American soldiers in France was 95,952, of which 67,295 were incapacitated as a result of disease and 28,660 from injuries.
